The slope of the exhaustion curve gives information on the rate of dyeing. The determination of these curves, however, requires much work, and they are dependent on the dyeing conditions and the nature of the goods. The dyeing rate is influenced by the temperature and by chemicals such as salts and acids, all of which also influence the final exhaustion. A clear distinction of the effects of process variables on the dyeing rate and on the final exhaustion at equilibrium is essential in the successful control of the dyeing process.

Initial Stage of Dyeing

The initial rate of dyeing (the initial slope of exhaustion versus time) is called the strike. Rapid strike by a dye often results in initial unlevelness and must be avoided for those dyes

that cannot subsequently migrate from heavily to lightly dyed areas of the fabric. For dyes of rapid strike, the dyeing conditions must limit the initial rate of exhaustion and therefore improve the levelness of the dyeing. The strike depends on the dyeing temperature, the dyeing pH, and the presence of auxiliaries.

Even for dyes of moderate and low strikes, the objective of uniform dyeing of the fiber mass is rarely achieved during the initial stages of the operation. This is because of irregularities in the material's construction, in the fiber packing, and in the distribution of residual impurities, as well as differences in temperature and flow rate of the solution in contact with the fibers.

Dye/Fiber Types and Dye Migration

Different types of textile fiber require different kinds of dyes, and in general dyes which are suitable for one type of fiber will not dye other types effectively.

The degree of exhaustion of a dye at equilibrium is higher the greater the substantivity of the dye for the fiber being dyed. Often, a very substantive dye will give a high initial rate of absorption, or strike. Substantivity is the "attraction" between dye and fiber whereby the dye is selectively absorbed by the fiber and the bath becomes less concentrated.

The ability of a dye to migrate and produce a level color, under the given dyeing conditions, is obviously an important characteristic. It can overcome any initial unlevelness resulting from a rapid strike. Migration of the dye demonstrates that the dye can be desorbed from more heavily dyed fibers and reabsorbed on more lightly dyed ones. This is especially important in package dyeing where uniform color of the yarn throughout the package is essential.

While migration is important for level dyeing, it has two major drawbacks. Firstly, dyes with greater ability to desorb from dyed fibers during migration will usually have lower fastness to washing. Dyes of very high washing fastness are essentially nonmigrating dyes for which level dyeing depends upon very careful control of the rate of dye uptake by the material. The second problem with migrating dyes is that good

migration may result in lower exhaustion, again because of their ability to desorb from the fibers.

Factors Affecting Levelness of Dyeing

As has been indicated dyeing is a very complicated process with different phenomena occurring simultaneously. Unlevelness can arise in many forms such as the unlevelness between sides, at ends of a fabric, or on the layers of a yarn package. The causes are as numerous as the effects. A quantitative analysis of the effects of many factors which influence the levelness of dyeing is a very difficult task since it would require the development of a mathematical model involving a significant number of parameters. Also, to investigate the transfer of dye through the substrate will involve the solution of nonlinear partial differential equations. Little work has been done on this aspect, according to the literature.

Flow Rate

During the dyeing process, the supply of dye through the solution to the surface of the fibers/yarns can occur in two ways, either by aqueous diffusion of dye through the liquor or by convective movements of the fluid which replace the depleted solution by fresh solution. Diffusion is a much slower process than the convective transport of dye, except at very low velocities of liquor flow.

However, an exact solution to the problem of convective diffusion to a solid surface requires first the solution of the hydrodynamic equations of motion of the fluid (the Navier-Stokes equations) for boundary conditions appropriate to the mainstream velocity of flow and the geometry of the system. This solution specifies the velocity of the fluid at any point and at any time in both tube and yarn assemblies. It is then necessary to substitute the appropriate values for the local fluid velocities in the convective diffusion equation, which must be solved for boundary conditions related to the shape of the package, the mainstream concentration of dye, and the adsorptions at the solid surface. This is a very difficult procedure even for steady flow through a yarn package of simple shape.

Measurement of Levelness

Although objective measurements have been proposed, the measurement of levelness and its causes is difficult. The levelling ability of dyes is routinely tested under a fixed set of circumstances, but the effect of changing circumstances is less often reported. Similarly, a distinction between levelness of strike and levelness from migration is not usually studied. A relatively simple means of determining levelness is via colorimetric measurement of dyed object in several locations representative of the entire substrate. A color difference metric may be used to determine the degree of variability across the substrate, and a tolerance volume may be established for this purpose. Visual assessments are also common, although these would be subjective and open to interpretation. A common procedure is to place side center side of a full width of dyed fabric to determine variations from center to sides due to variations in processing conditions. Such variability is called tailing. Another common type of variability in continuous operations is due to variability in the composition of the trough during the dyeing process that may generate shade variation between the beginning and the end of a roll, commonly denoted ending. Some online measurement systems have been proposed and used in some cases, in which digital imaging or colorimetric systems are installed in a continuous processing line which can alert the operator to “larger than expected” variations in color during the operation.

Dyes

A dye is a substance capable of imparting its color to a given substrate, such as a textile fiber. A dye must be soluble in the application medium, usually water, at some point during the coloration process. It must also exhibit some substantivity for the material being dyed and be absorbed from the aqueous solution.

For diffusion into a fiber, dyes must be present in the water in the form of individual molecules. These are often colored anions, for example, sodium salts of sulfonic acids. They may also be cations such as mauveine or neutral molecules with slight solubility in water, such as disperse dyes. The dye must have some attraction for the fiber under the dyeing conditions so that the

solution gradually becomes depleted. In dyeing terminology, the dye has substantivity for the fiber and the dyebath becomes exhausted.

The four major characteristics of dyes are:

1. Intense color
2. Solubility in water at some point during the dyeing cycle
3. Substantivity for the fiber being dyed
4. Reasonable fastness properties of the dyeing produced

The structures of dye molecules are complex in comparison with those of most common organic compounds. Despite their complexity, dye structures have a number of common features. Most dye molecules contain a number of aromatic rings, such as those of benzene or naphthalene, linked in a fully conjugated system. This means that there is a long sequence of alternating single and double bonds between the carbon and other atoms throughout most of the structure. This type of arrangement is often called the chromophore or color-donating unit. The conjugated system allows extensive delocalization of the p electrons from the double bonds and results in smaller differences in energy between the occupied and unoccupied molecular orbitals for these electrons. At least five or six conjugated double bonds are required in the molecular structure for a compound to be colored.

Table 1 gives partial classifications of dyes as presented in the Colour Index International [8]. In order to gain an optimum result, the appropriate dye class for the fiber must be used, along with specific dyeing conditions. The ten major dye classes involve acid, metal complex, mordant, direct, vat, sulfur, reactive, basic, disperse, and azoic dyes. Some of ten major dye classes shown in Table 1 can be used to dye the same fiber type, but varying conditions are required. For example, acid, metal complex, mordant, and reactive dyes can all be used to dye wool. However, there may be one type of dye that is preferred for a certain dyeing process, for example, disperse dyes for polyester fibers.

There are numerous factors involved in the selection of dyes for coloring textile materials in a particular shade. Some of these are:

Coloration, Textile, Table 1 Classification of dyes according to chemical constitution and usage

Classification of dyes according to chemical constitution	Classification of dyes according to textile usage
Azo	Direct
Anthraquinone	Azoic
Heterocyclic	Vat
Indigoid	Sulfur
Nitro	Reactive
Phthalocyanine	Acid
Polymethine	Basic (cationic)
Stilbene	Disperse
Sulfur	Mordant (metal complex)
Triarylmethane	

- The type of fibers to be dyed
- The form of the textile material and the degree of levelness required – level dyeing is less critical for loose fibers, which are subsequently blended, than it is for fabric
- The fastness properties required for any subsequent manufacturing processes and for the particular end use
- The dyeing method to be used, the overall cost, and the machinery available
- The actual color requested by the customer

The approximate relative annual consumption of the major types of fibers and dyes estimated in the year 2000 indicates that dyes used for cotton (the most widely used natural fiber) and for polyester (the most widely used synthetic fiber) dominate the market. In the case of cellulosic fibers including cotton, reactive dyes due to possessing excellent fastness properties upon fixation and demonstrating bright and brilliant shades occupy the lion's share of the market for this fiber category. Disperse dyes also occupy a large sector of the market due to their use on polyester fibers. Other colorants occupy smaller sections of the market and their applications are specific and less common.

Sorption Isotherms

In order to determine the thermodynamics of dye sorption by various fibers three main models have

been proposed. These are known as Nernst, Langmuir, and Freundlich sorption isotherms [9]. These models determine the relationship between the concentration of dye in fiber and that in solution under isothermal dyeing conditions. In the simplest form the relationship is linear (Nernst). The Nernst isotherm indicates that the distribution of dye between fibers and bath is simply due to the partition of the dye between two different solvents until one becomes saturated. In a more complex scenario, dye "sites" are present in the fiber which result in an apparent saturation value. These sorption processes are defined by the Langmuir isotherm. In some cases an empirical power function, represented by the Freundlich model, can be used to determine the relationship between the amount of dye in solution and that in fiber. An examination of this model shows that the exhaustion of dye drops towards the end of the dyeing cycle. The drop in percent exhaustion with an increase in the depth of dyeing is well known and reflects the loss of activity of the dye in solution with increasing concentration. According to this model there appears to be no saturation value for the fiber, and as more and more dye is added to the bath, more and more is taken up. There is of course a practical limit as to how much dye may be placed on the fiber. An example of a system that can be described by the Nernst isotherm is the dyeing of polyester fibers with disperse dyes. Acid dyes on wool or basic dyes on acrylic are attracted to specific dye sites with opposite charge, and these would exhibit Langmuir-type relationships. The adsorption of direct dyes on cotton may be described by a Freundlich model however, where no specific dye sites are present in fiber but a gradual decrease in the overall rate of dye adsorption is witnessed over time. In general Freundlich models are indicative of nonionic or relatively weak bonding possibilities between dye and fiber.

Summary

Many aspects of dyes and dyeing have not been covered. This is due to the complexity of the process and the large number of variables and processes involved. Textile coloration is a large

industry, and a number of excellent resources are available that cover the fundamentals of coloration and the dyeing of specific types of fibers. The reader should refer to additional resources for a detailed examination of the topics.

Synonyms

[Color-opponent processing](#); [Focal colors](#); [Hue opponency](#)

Definition

Unique hues are colors that cannot be described by any other color term than their own. There are four unique hues: red, green, blue, and yellow. Unique hues emerge at the equilibrium points of the color-opponent mechanisms: a color which appears neither reddish nor greenish is a unique yellow or unique blue; a color which appears neither yellowish nor blueish is unique red or unique green.

Historical View

Four colors occupy a special place in color perception. They are called unique hues and they originate from the opponent color theory proposed by Ewald Hering in 1878 [1]. Hering was the first to notice that some pairs of colors, namely, red and green, and yellow and blue, cannot be perceived at the same time. He named these pairs of colors “Gegenfarben” [opponent colors], since they are mutually exclusive colors as indicated by the lack of overlap between red and

Color-Opponency, Unique Hues, Fig. 1 Hering [1], page 42. The opponent colors, red vs. green, and yellow vs. blue, are mutually exclusive. This idea is conveyed in Hering's original figure by showing that there is no overlap between red and green, or between yellow and blue

green, and between yellow and blue in Hering's original figure (Fig. 1). Hering's color vision theory postulates three opponent processes: two chromatic processes of red-green and blue-yellow and one achromatic process of light vs. dark. Unique hues are perceived when one of the two chromatic processes is polarized in one direction and the other opponent process is at equilibrium. For example, the putative yellow-blue mechanism signals colors from yellow to blue; if the stimulus contains neither yellow nor blue, then it elicits no response (Fig. 2) and this mechanism is deemed to be at equilibrium. Stimuli that are perceived as "neither yellow nor blue" are defined as "unique red" or "unique green," depending on which side of the neutral grey point they are located. Likewise, colors that silence the red-green opponent mechanism are called "unique yellow" or "unique blue". Hurvich & Jameson [1] were the first to use a hue cancellation procedure to find the equilibrium points (null responses) of Hering's color-opponent mechanisms.

The opponent-color vision theory was initially thought to be at odds with the trichromatic theory proposed by Thomas Young in 1802 and developed by Hermann von Helmholtz in 1850. The trichromatic theory states that there are three types of receptors responsible for conveying color

Color-Opponency, Unique Hues, Fig. 2 The response of a hypothetical yellow-blue mechanism is shown

signals. These two theories of color vision were the focus of controversy among scientists until they were integrated into the two-stage model in the 1960s [2]. The trichromatic theory holds at the receptor level in the retina where there are three types of cones. These are called short-, medium-, or long-wavelength-sensitive (S, M, or L) cone receptors, and the names are derived from the different spectral region of the peak in their spectral sensitivities. After light is absorbed in the three classes of cone receptors (S, M, L), the outputs of the receptors are combined in an opponent fashion, both at the retinal ganglion cell level and again at later processing stages in the visual cortex [3]. Therefore, the trichromatic theory of color vision and the opponent-color theory are not at odds with each other; rather they reflect different processing stages in the visual pathway, namely, photoreceptors in the retina versus retinal ganglion cells/LGN and cortical processing.

Behavioral Evidence for Unique Hues

Color-normal observers are readily able to adjust lights such that they appear "neither yellowish nor blueish" or "neither reddish nor greenish" without any training or detailed instruction, but attempts to provide conclusive behavioral evidence for the privileged role of these four hues have been unsuccessful. Traditionally, unique hues have been measured with spectral lights created by a monochromator to show a light of only one wavelength [4]. More recently, Kuehni and colleagues [5] have used broadband stimuli such as those

Color-Opponency, Unique Hues, Fig. 3 Unique hue settings for 185 color-normal observers [11] are plotted in an approximately uniform $u'v'$ diagram. Symbols are proportional to the number of data points. The solid, dashed, and dotted lines indicate the first principal component for the dark, D65 (daylight simulator) and CWF (office light) viewing conditions, respectively

printed on paper (Munsell Color chips; Natural Colour System chips [6]), while stimuli presented on a computer screen have also been widely used [7].

Larimer and colleagues [8, 9] were the first to test the linearity and additivity of the color-opponent mechanisms. The red-green equilibria are approximately linear; that is, unique yellow and blue are co-linear; the yellow-blue equilibria on the other hand are not linear, that is, unique red and green do not lie on a line through the origin, the neutral grey background (Fig. 3; [10]). Furthermore, unique yellow and unique blue are fairly color constant in comparison to unique green and red: the unique yellow and blue settings are not affected by the changes in the ambient illumination (“Dark,” “D65,” “CWF,” Fig. 3).

Unique hues are defined as the hues that emerge at the equilibrium points of the putative color-opponent mechanisms [8, 9] (see Fig. 2). In the two-dimensional $u'v'$ chromaticity diagram, this can be formalized as follows:

$$YB_R = \alpha_R \times \Delta u' + \beta_R \times \Delta v' = 0 \quad (1)$$

where $\Delta u'$ and $\Delta v'$ are the incremental chromaticity coordinates of the unique red settings with

Color-Opponency, Unique Hues, Table 1 Coefficients of mechanisms at equilibrium

Unique hue	Orthogonal vector	Orthogonal vector coefficients (SD)	
		α	β
Red	YB_R	$-0.206 (0.050)$	$0.977 (0.008)$
Green	YB_G	$0.408 (0.511)$	$0.526 (0.545)$
Yellow	RG_Y	$0.926 (0.025)$	$-0.370 (0.063)$
Blue	RG_B	$0.838 (0.028)$	$-0.542 (0.049)$

respect to a grey background. α_R and β_R are the respective weights of the yellow-blue mechanism (YB_R) which is silenced by unique red. Similarly, the orthogonal vector for unique green is defined as:

$$YB_G = \alpha_G \times \Delta u' + \beta_G \times \Delta v' = 0 \quad (2)$$

To generate unique yellow (unique blue), a red-green opponent mechanism (RG) is assumed to be at equilibrium, hence the orthogonal vectors are defined as follows:

$$RG_Y = \alpha_Y \times \Delta u' + \beta_Y \times \Delta v' = 0 \quad (3)$$

$$RG_B = \alpha_B \times \Delta u' + \beta_B \times \Delta v' = 0 \quad (4)$$

To a first approximation, the unique green vector is orthogonal to the unique blue and the unique yellow lines (cf Fig. 3), hence the direction of the RG_{YB} mechanism is aligned with the unique green line (Table 1). This means that observers use a hue close to unique green when asked to cancel the greenish tint in a hue cancellation task. In contrast, the unique red line is not aligned with the orthogonal vector for unique yellow or blue ($RG_{Y,B}$). Hence, when observers are asked to cancel the reddish tint in a hue cancellation task, their “internal red” is not the same as their unique red settings, but is much more bluish than their unique red.

The lack of collinearity of the unique red-green line and the failure of orthogonality of these two hue-opponent mechanisms is not a consequence of the particular chromaticity diagram used, but is an intrinsic property of hue opponency which is

also revealed in the a^*b^* chromaticity diagram (CIECAM02) and physiologically motivated chromaticity diagrams (see Fig. 4 below).

Neural Basis of Unique Hues

The discovery of neurons with chromatically opponent receptive fields in the retina and the Lateral Geniculate Nucleus (LGN) [11] initially led to the erroneous suggestion that these neurons constitute the physiological substrate of Hering's color-opponent processes and consequently, the unique hues. It is now clear that these early cone-opponent mechanisms are not the neural substrate of the behaviorally measured hue opponency [3, 12]. The discrepancy between hue opponency and cone opponency is readily seen by re-plotting the unique hue loci in a cone-opponent diagram (Fig. 4) where the x axis reflects the activity of the L-M cone-opponent mechanism and the y axis that of the S-(L + M) cone-opponent mechanism. These cone-opponent color directions are sometimes referred to as "cardinal directions" of color space [12].

The unique hue lines are not aligned with the cone-opponent axes [12]. The red-green equilibria (=line connecting unique yellow and blue) are not parallel to the S/(L + M) cone axis; the yellow-

blue equilibria (=line connecting unique red and green) are not aligned with the L/(L-M) axis. Unique blue requires, in addition to the S cone input, an M cone input; unique yellow requires a negative S cone input, and a positive L cone input. Similarly, unique green requires a negative S cone and a positive M cone input. Unique red is the only hue that is at least approximately aligned with the L/(L + M) axis; but even here a systematic negative S cone input is required. Since early cone-opponent mechanisms do not constitute the neural mechanisms underlying the observed hue opponency and the resulting unique hues, further re-combinations of the early cone-opponent signals must occur between the LGN and the primary visual cortex, or within the visual cortical areas [3, 13].

The cone-opponent signals from the LGN undergo another chromatic transformation when reaching the primary visual cortex [13]. This re-combination of color signals was directly tested using fMRI decoding techniques in the LGN and visual cortex [14, 15]. Modulations along the cone-opponent (red-green, lime-violet axes in Fig. 4; denoted as "Cardinal Colors" in Fig. 5) and light-dark directions can be decoded in LGN, but not in the primary visual cortex, V1. Conversely, unipolar modulations between the grey background and a particular unique hue can be

Color-Opponency, Unique Hues,

Fig. 4 Unique hue settings for 185 color-normal observers [11] are plotted in the cone-opponent diagram based on the CIE 2006 2-deg cone fundamentals. The grey background is shown as an 'x'. Lines denote first principal components

Color-Opponency, Unique Hues, Fig. 5 Classification performance for cardinal colors and for unique hues in the LGN (left) and primary visual cortex (right). Dashed lines indicate 95% confidence limits

decoded in V1, but not in LGN (denoted as ‘Unique Hues’ in Fig. 5).

Successful classification of cardinal colors in the LGN is consistent with the known spatial clustering in layers of neurons tuned to cone-opponent color modulations [11] and the failure to decode cone-opponent modulations in V1 is consistent with cortical chromatic tuning properties different from those found in the LGN. The successful decoding of unipolar hue modulations corroborates evidence of a hue map in V1, but does not constitute strong evidence for the special status of unique hues.

Individual Differences

To a first approximation, unique hue judgments are robust across different cultures and languages [16], but there are variations in the unique hue loci among people with normal color vision [17]. The sources of these individual differences remain unknown. Possible physiological sources of individual differences include pre-receptoral light filtering by the lens and macular pigment, spectral sensitivity and optical density of cones, relative number of different types of cones, and relative sensitivity of the two chromatic mechanisms at the second stage. Among these possibilities, variations in pre-receptoral filtering and optical

density of cones are not large enough to account for observed individual differences in unique hues [18]. The L/M cone ratio can vary by more than a 30-fold range among individuals, and it is far too large to account for the range of observed unique hue differences [17] and unique yellow settings have been shown to be independent of the L:M cone ratio [19]. Furthermore, no robust relationship has been found between the variability in the cone-opponent mechanisms and the variability in unique hue settings, hue scaling, and hue naming tasks [20]. In contrast to chromatic sensitivity, unique hue loci are remarkably stable across the lifespan [10, 21].

Cultural and Environmental Factors

Since unique hue loci are not significantly constrained by optical factors or low-level color mechanisms, it is likely that environmental factors play a role in the emergence of unique hues. For example, unique hue loci correspond to surface reflectance that are optimally color constant when illuminated by natural daylight [22]. However, cultural factors are entwined with environmental factors since the distribution of colors available in a particular environment will shape the range of colors utilized by a particular culture. Differences in unique hue loci between observers in India and

the United States have been documented [23], but the inter-group variations are relatively small compared to the within-group variation. Differences in unique hue loci across different cultures are likely to reflect the interplay between particular languages spoken, cultural norms, and environmental factors. The neural plasticity of these higher-order color mechanisms may be useful to compensate for age-related physiological changes such as the yellowing of the lens, differences in the retinal make-up including the L:M cone ratio, and changes in the chromatic environment [24].

Unique Hues and Focal Colors

To evaluate the universality of color terms across languages, color naming data from native speakers of 20 languages were collected [25]. A palette of Munsell color chips was presented to human observers with the instruction to choose a best example of the color term and to draw a boundary of the chips that can be called by the color term. Though their origins are completely different, unique hues and focal colors for categories red, green, blue, and yellow have been shown to closely correspond with each other empirically [26].

Summary

Unique hues are the four primary colors in color perception. The neural basis of the four unique hues is still a mystery, but it is clear that the cone-opponent mechanisms in the early visual pathway are not the neural substrates of the unique hues. These early cone-opponent mechanisms must undergo further transformations to lead to a representation of the unique hues in cortical visual areas.

Unique hues are robust across the life span but individual differences in the unique hue loci exist. The sources of these individual differences have not yet been identified, but peripheral

physiological factors have been excluded as the main source of individual variation. The emerging picture is that unique hues are shaped by both environmental factors resulting in long-term adaptation as well as cultural factors.

Colors: Where Are They?

Susan P. Farnand¹ and Rolf G. Kuehni²

²Color Science Laboratory, Carolina State University, Raleigh, NC, USA

Statement of the Question

Most people with normal color vision would agree that ripe strawberries are red, summer leaves are green, and the sky is blue. But, are red and green actual properties of berries and leaves? Are strawberries actually red and leaves green? Or, do these colors only exist in the minds of viewers? Expert opinions, recorded first in the early seventeenth century, generally indicate a greater likelihood of the subjective nature of the color experience, comparable to other sensory experiences, located only in the minds of creatures with a color vision system. Color scientists would contend that colors are not just related to object properties but are a product of the light interacting with the object to trigger a response in the eyes and brain of the observer. To understand the subjective or objective nature of color, we must understand the properties of light and the visual system of the observer, as well as properties of the object.

The idea that colors (and other sensory experiences) exist only in consciousness was probably expressed for the first time in writing in a book published in 1623 by Galileo Galilei who said “I think that tastes, odors, colors, and so on are no more than mere names so far as the object in which we place them is concerned, and that they reside only in the consciousness.” [1]

More recently Steven Pinker stated the following: “Our minds evolved by natural selection to solve problems that were life-and-death matters to our ancestors, not to commune with correctness.” [2] This comment makes clear that the question of the source of color perception is not unique

but that the same situation applies to all sensory perceptions, including smell, taste, and hearing.

Light as a Primary Cause of Color Perception

Color perception requires light. So, the first question to be considered is: what is light? People have argued about this for millennia, and a scientifically solid answer still does not exist. Over the centuries, light has alternatively been described as consisting of waves or particles. The weight of Isaac Newton's opinion helped bolster the argument of light as a particle until the time of Young's double slit experiment, which swayed description of light back to waves. This was reinforced by Maxwell's introduction of a theory of electromagnetic radiation (EMR) [3]. This explanation held until Einstein's Quantum Theory of Light, which described light as packets of energy known as photons. Most expert authors now describe light as having both a wave and a particle nature. In either case, it can be said that the experience of natural light is the perceptual response of most living creatures to a narrow band of electromagnetic energy that travels from the sun directly and indirectly to the earth. As wave energy, the band of wavelengths representing light (for humans) ranges from about 370 nanometers (nm) to about 750 nm. It is a small range of EMR, but enough to be able to provide considerable information about its immediate source without containing the shorter wavelengths energy that is damaging to the visual systems of most living creatures and is largely filtered by the Earth's atmosphere.

Humans have wondered for centuries if EMR in the form of perceived light from the sun also carries colors in it. An answer, based on extensive experimental experience, was provided by Newton in his 1704 book *Opticks*, in which he said "For rays to be spoken properly are not coloured. In them is nothing else than a certain power and disposition to stir up a sensation of this or that colour" [4]. This can be demonstrated, in a typical office or classroom setting, by passing a spectrally narrow beam of light, such as that from

a laser pointer, approximately horizontally in front of our eyes. Unless there is dust in the air that reflects some of the light, we will not see the beam or experience any colors unless it is reflected from a surface into our eyes.

The Visual System Is the Creator of Color Perceptions

The human visual system integrates the spectral response to light and colorant mixtures. Because of this, identical perceptual results for color-normal observers to a given mixture of lights of varying wavelengths or colorants of varying reflectance functions can be obtained with many different mixtures of lights or colorants. An extreme example of this phenomenon, which is known as metamerism, is shown in Fig. 1. Two versions of reflectance functions of a medium lightness gray are depicted. When viewed by color-normal observers under standard conditions of lighting and surround, the appearance of the two samples will be identical despite the large difference in reflectance functions. This can be mathematically predicted using the system of experimentally determined color matching functions, $\bar{x}$, $\bar{y}$, and $\bar{z}$ (Fig. 2) [5]. With them, related tristimulus values X , Y , and Z can be calculated based on reflectance functions representing the color samples involved. For the reflectance functions of Fig. 1 and a uniform light source under which the samples are viewed, the tristimulus values X , Y , and Z are identical for both samples, indicating that they will be perceived by color-normal humans as identical in color. A large number of samples having the same tristimulus values but different reflectance functions can be created, depending on the available colorants.

In the metamerism example described above, the two sample colors having different spectral curves that match under one light source may appear to have quite different colors under another light source. Because the visual response integrates the spectral curves of the light source and the sample relative to the sensitivity of the viewer (the personal color matching functions), observer metamerism may also occur. In this case, two

Colors: Where Are They?,
Fig. 1 Two theoretical reflectance functions representing colored materials that by the CIE 1931 standard observer are seen as having identical gray appearance, based on the related color matching functions of Fig. 2. In both cases X, Y, and Z have identical values of 50.0 each

Colors: Where Are They?,
Fig. 2 CIE 1931 standard colorimetric, 2°, color matching functions. The colors used are arbitrary and do not represent any relation to perceived colors

spectrally different colorants or lights may match for one color-normal observer but less so or not for another, due to small but sometimes significant differences in human visual systems. Metamerism means that the trichromatic human visual system is seriously limited in its capability of distinguishing between different sets of EMR arriving at the eyes as reflected from the surface of the colored samples or from self-luminous stimuli.

As mentioned, a perceptual response to light requires a system that is sensitive to EMR and is capable of interpreting in some way the responses of the sensors. Without this, we would not be

aware of lights, as fully blind people can confirm. The animal/human experience of light is the result of the specific response of the visual system to the stimulation by selected EMR levels entering the eyes. A system with a single type of sensor (a monochromatic system) cannot provide distinction between spectrally different levels of energy (or wavelengths) of the radiation impacting on it. At least two or more sensor types with sensitivities to different wavelength ranges are needed, together with an interpretation system, to provide a degree of distinctiveness of different wavelength levels of the EMR.

The development of such a system began with light-sensitive cells, which were originally likely used for orientation of the organism toward or away from the sun. All multi-cellular organisms possess the genetic toolkit for such photoreceptors. Fossil evidence indicates that the first eyes appeared early in the Cambrian period (543 to 538 MYA). At that time, “an explosion of life” occurred that resulted in the development of all the current existing phyla and that some authors, such as Andrew Parker in his book *In the Blink of an Eye*, attribute to the advent of vision [6]. Most argue that this macroevolution was more complex than that and involved such conditions as the presence of oxygen in air and a warming climate. During the Cambrian explosion, trilobites (and other living creatures) evolved which had complex seeing capabilities. They had a frontal head with two-eye structures comprising some 150 visual cells, each with its own minute lens and a single light sensor below it. The results from these sensors fed into the brain. Animals having compound eyes, including many arthropods, are still in existence today.

For the creatures with early eyes based on single kinds of light receptors, the resulting achromatic percepts of potential food, enemies, or partners were clearly very useful, but additional more detailed information regarding the nature of objects in front of their eyes was obviously also supportive. Accordingly, a kind of light sensor known as cones also began to develop. Cone sensors with sensitivity to different ranges of EMR of light resulted in more specific information about the surrounding world. This more detailed input from the cone sensors having different spectral sensitivities required more complex brain systems to interpret. When cone sensors first developed is not known, but by ca. 500 MYA, jawless vertebrate fish are believed to have had four types of cones with different spectral sensitivities [7]. The presence of two or more cone types differing in spectral sensitivity in an eye resulted in some loss of image sharpness but in a gain of more qualitative information about the fishes’ surroundings, expressed in form of color vision.

The development of mammals began around 150–200 MYA. They were mostly nocturnal and thereby not in need of four cone types. They developed simple dichromatic color vision systems. Dichromatic mammals continue to be the norm, with some important exceptions. Early primates, such as lemurs, which essentially lived in trees, required quick and detailed distinction of elements of their arboreal environment and, consequently, developed a trichromatic vision system with stereopsis, the overlapping in the brain region of information from both eyes, allowing for depth perception which was important for more accurately assessing distances of food sources or enemies. The old-world primates, including gorillas and chimpanzees, also had and have a trichromatic stereoptic visual system. Our direct ancestor, homo sapiens, began life ca 300 TYA in Africa. Like earlier human ancestral groups, they were trichromats, with short, medium and long (S, M and L) cone types in the eyes. The human M cones have spectral sensitivity relatively close to that of L cones, as Fig. 2 shows.

The electric signals generated when cone cells absorb light are transmitted to the brain through horizontal, bipolar, amacrine, and ganglion cells, all of which are located in the retina. The connections between different layers are complex. The information produced by the ganglion cells is passed through the lateral geniculate nucleus into the occipital lobe of the brain at the back of the head where additional visual processing takes place. The color perception-generating apparatus in the retina and the brain/mind is quite complex. While significant progress has been made in understanding the visual system in humans, all its details are not yet known. In whatever way it may be accomplished, the final result is the experience in our mind of colored images of the outer world. Specific colors experienced in this fashion can be related to specific wavelengths of light, but most sensations are based on broadband mixtures of EMR stimuli.

There are considerable differences in the visual systems in the animal kingdom. Creatures with color vision have between 2 and 40 different visual sensor types, resulting in different

approaches to interpreting EMR signals. The silver spinyfin, a deep-sea fish, has 2 cones and 38 rod opsins to provide detailed information in the spectral range of bioluminescence if present as well as the daylight that reaches their environment [7]. Humans with normal color vision are trichromats, having sensors with peak sensitivities in the eye at approximately 440, 530, and 558 nm.

Colors we experience are the result of the interpretation of input sensory signals in our brains/minds, as are all other sensory experiences. Metamerism demonstrates that the visual system, depending on the number of sensor types, has stronger or weaker capability to identify and distinguish between spectrally different kinds of EMR in the visible range. Different animals have different visual systems and so can distinguish different elements in their environments. For example, bees and some birds have sensitivity in the ultraviolet region, but not in the longer wavelength region of the human visible spectrum. Some insects and the mantis shrimp can detect polarized light. The visual systems of these animals are adapted to interpret environmental information according to their specific needs. There is no reason to expect that how they see nature would match how humans see it.

There is also no reason to expect that the color experience of humans with normal color vision would be fully identical. Evidence suggests that it is not. As mentioned with regard to observer metamerism, there are small but measurable differences in observer color matching functions. Understanding observer differences has been an area of active research in recent years [8, 9].

Along with metamerism, there are other phenomena that demonstrate the variable relationship between physical measurements of the interaction of objects and light and the appearance of color. These include simultaneous contrast, chromatic adaptation, and memory colors. Please refer to the relevant entries for additional information.

Light and colors remain personal experiences that we cannot describe in a meaningful objective way, as it is the case with all other sensory experiences we have. We can identify the physical or chemical stimuli that produce these experiences but not the experiences themselves. Given the

physical results of stimulus mixture, as shown in the CIE colorimetric system, we can predict the results of such stimulus mixtures but with prediction of the perceived results only in form of assumed identity of perceived color experiences for all “color-normal” observers. Experimental assessments of the stimuli of so-called primary hues red, blue, yellow, and green can result in reasonable mean agreement between groups of observers, but there is significant interobserver variability in the selections, indicating sources of variability in the perception processes.

It is an undisputable fact that the color experiences humans have are generated in our brains/minds. Are they perceptual interpretations in brain/mind of the EMR signals arriving at the eyes, based on a mechanism that life generated over millions of years? Or are they reconstructions of colors out in the world based on the EMR patterns arriving at the eyes? A scientifically based direct or indirect solid argument for colors being in the outside world has as yet not been offered.

Authors of existing scientific books on color vision generally did not address this issue. An exception is the psychologist and academic Stephen E. Palmer, author of the 1999 book *Vision Science, Photons to Phenomenology*, in which he stated (Chap. 3): “People universally believe that objects *look* colored because they *are* colored . . . The sky looks blue because it *is* blue, grass looks green because it *is* green, and blood looks red because it *is* red. As surprising as it may seem, these beliefs are fundamentally mistaken.” [10]

In *The Case Against Reality: Why Evolution Hid the Truth from Our Eyes*, [11] the author, Donald Hoffman, a professor of cognitive science, addresses in significant detail the related issues of our sensory experiences. He shows, with logically solid arguments, that the world we experience is not the real, physical world but one that evolution generated for all living systems to provide information to the system owners. It provides not physically truthful information but information that simplifies their worlds and their actions in them: colors, smells, tastes, sounds, etc.

Hoffman cannot, as yet, offer totally indisputable evidence for his claims. Presently, we still lack full understanding of the relationship between the physical world and the perceptual world of living creatures. There is much work to be done in the coming decades.

The idea that colors and other sensory experiences are in reality the interpretations of available physical information needed for survival and exist only in the bodies/minds of living creatures will likely become more and more acceptable as time goes on.

Colour Index

Geoffrey Hallas

Department of Color Chemistry, University of Leeds, Leeds, UK

Definition

Online database of colorants (dyes and pigments), published jointly by the Society of Dyers and Colorists (SDC) and the American Association of Textile Chemists and Colorists (AATCC). The Colour Index uses a dual classification system in which the prime descriptor is the Colour Index Generic Name (often abbreviated to CIGN), which is related to application (usage). The other descriptor is the Colour Index Constitution Number (often abbreviated to CICN), which is related to chemical structure.

Overview

Historical

First Edition

Early attempts to list and classify synthetic dyes and pigments, involving chemical structure and hue, appeared before the end of the nineteenth

century [1]. The most successful system at this time was the Farbstofftabellen of Gustav Schultz (with seven editions between 1888 and 1932, followed by Supplements to the Seventh Edition in 1934 and 1939); each colorant was given a classification number. Meanwhile, from 1922, the Society of Dyers and Colorists published a series of 12 monthly compilations, which culminated in the First Edition of the Colour Index, edited by F. M. Rowe, as a bound volume in 1924; as well as synthetic organic colorants (1230 entries), the 750-page volume contained sections on natural organic colorants and inorganic colorants. A Supplement was published in 1928, the bulk of which consisted of a new alphabetical index of commercial names.

Second Edition

After the Second World War, and the disclosure of detailed information on the products of German manufacturers, there was a pressing need for a revised up-to-date edition. In collaboration with the American Association of Textile Chemists and Colorists, the Society of Dyers and Colorists began this mammoth task that took over a decade to complete. It was recognized that the Second Edition of the Colour Index had three functions: (i) to correlate the different commercial names of individual dyes, (ii) to provide information on the mode of application, fastness properties, solubility, and so on, and the established usage of current commercial dyes, (iii) to provide information on the chemical structure and components, and mode of preparation of technical dyes, and to supply relevant literature and patent references.

The first volume of the new edition was published at the end of the Perkin Centennial year (1956). On completion, Part 1, the first two volumes, covered Technology and Commerce. Dyes and pigments were classified according to usage and were arranged in spectral hue order. Each colorant was given a usage name and number, known as the C.I. Generic Name (CIGN), e.g., C.I. Acid Yellow 23 and C.I. Pigment Blue 15. Methods of application, usage, and fastness properties were also included. Part 2, volume 3, covered the classification of dyes and pigments

according to their chemical constitution; an index of intermediate compounds was also given. Each colorant was allocated a five-figure number, known as the C.I. Constitution Number (CICN), e.g., C.I. 19,140 (for C.I. Acid Yellow 23) and C.I. 74,160 (for C.I. Pigment Blue 15). Methods of manufacture, inventors, and literature references were provided. Part 3, volume 4, consisted mainly of an alphabetical list of commercial names together with CIGNs and CICNs; cross-references to numbers used in the First Edition of the Colour Index and in the final edition of Farbstofftabellen were included. Overall, the new edition covered over 3500 unique colorants; a Supplement was published in 1963, an important feature of which was the introduction of C.I. Reactive Dyes as a new usage group. The new edition was updated by the publication of a series of Additions and Amendments, mostly quarterly, between late 1958 and the end of 1970.

Third Edition

Publication of the Second Edition established the Colour Index as the leading reference work for the classification of colorants and, by the end of 1963, copies had been supplied to over 50 countries. Collation of information for the publication of a Third Edition of the Colour Index began during 1965 and, again, there was collaboration between the SDC (Editorial Board) and the AATCC (Editorial Committee), a formal agreement being signed during 1969. The completely revised and enlarged Third Edition was published in five volumes at the end of 1971. The first three volumes (Part 1) cover technical information and classification by usage and volume 4 (Part 2) deals with chemical information and classification by structure; this volume also contains an alphabetic Intermediates Index and an Elementary Formula Index. At the time, volume 4 contained current as well as historical structural information. Commercial information is found in volume 5 (Part 3) under a Generic Names Index (which includes relevant C.I. Constitution Numbers) together with an alphabetic index. As with the Second Edition, the various volumes are paginated with four-figure numbers, the first digit in each number

indicating the volume in which that page is to be found [2].

The technical information provided in Part 1, listed under C.I. Generic Names, follows the alphabetical usage (application) sequence Acid Dyes, Azoic Colorants, Basic Dyes (volume 1), Developers, Direct Dyes, Disperse Dyes, Fluorescent Brighteners, Food Dyes, Ingrain Dyes, Leather Dyes (volume 2), Mordant Dyes, Natural Colorants, Oxidation Bases, Pigments, Reactive Dyes, Reducing Agents, Solvent Dyes, Sulfur Dyes, Condense Sulfur Dyes, and Vat Dyes (volume 3). Within each dye class, the hue order is yellow, orange, red, violet, blue, green, brown, and black; in the case of pigments, the list is extended to include white and metal. Where known, the relevant C.I. Constitution Numbers are given. The hue or shade is defined according to a Colour Index Hue Indication Chart.

The structural information provided in Part 2 (volume 4) is listed under C.I. Constitution Numbers (CICNs) contained within various chemical classes; related C.I. Generic Names (CIGNs) are included where appropriate. Each essential colorant is allocated a separate five-figure CICN. Where dyes or pigments differ only in the metal or acid used for salt formation, a subdivision has been made by addition of a sixth figure after a colon. The absence of a CIGN signifies a colorant of historical significance or a product no longer manufactured (some of these examples have been allocated CIGNs subsequently). In each category, the various colorants are arranged strictly on the basis of their chemical structures; consequently, dyes and pigments that are chemically related, but belong to different application classes, can be found together.

The main structural categories used to classify colorants in volume 4 (with CICN ranges shown in parentheses) are Nitroso (10000–10299), Nitro (10300–10999), Monoazo (11000–19999), Disazo (20000–29999), Trisazo (30000–34999), Polyazo (35000–36999), Azoic (37000–39999), Stilbene (40000–40799), Carotenoid (40800–40999), Diphenylmethane (41000–41999), Triaryl methane (42000–44999), Xanthene (45000–45999), Acridine (46000–46999), Quinoline (47000–47999),

Methine and Polymethine (48000–48999), Thiazole (49000–49399), Indamine (49400–49699), Indophenol (49700–49999), Azine (50000–50999), Oxazine (51000–51999), Thiazine (52000–52999), Sulfur (53000–54999), Lactone (55000–55999), Aminoketone (56000–56999), Hydroxyketone (57000–57999), Anthraquinone (58000–72999), Indigoid (73000–73999), Phthalocyanine (74000–74999), Natural Organic Coloring Matters (75000–75999), Oxidation Bases (76000–76999), and Inorganic Coloring Matters (77000–77999). The final category contains both natural and synthetic products, classified under their metals and listed alphabetically in the order metal (in a few cases), oxides, hydroxides, and then other compounds in anion sequence. In the case of compounds containing more than one metal, the listing is under the metal mainly responsible for the coloring properties of the product.

Incorporated within many of these ranges of organic colorants are further structural subclasses. The description of each class of colorants is preceded by a brief account of the characteristics of its members. Typical structures are usually shown and, where the class comprises a variety of chemical types, the order in which these are dealt with is explained. Within a particular class, simpler colorants precede more complex structures, with aliphatic derivatives appearing before aromatic compounds, which follow the order benzene, naphthalene, anthracene, and heterocyclic types. The colorants in each chemical class are usually arranged accordingly as they contain amino, hydroxyl, or both amino and hydroxyl groups. The arrangement within the various subclasses is, in general, in the substituent sequence halogen, nitro, acylamino, carboxamido, sulfonamido, and sulfonyl. In the case of azo colorants, compounds devoid of carboxylic acid and sulfonic acid groups are separated from those containing these substituents in order to bring together usage groups such as Disperse Dyes, Solvent Dyes, and Pigments which otherwise would be widely scattered. More comprehensive details of chemical progression are provided at the start of each class or subclass, as appropriate.

The first hard copy supplement to Volumes 1 to 4 was published in 1975, as volume 6, together with the first revision of volume 5. A supplement to Volumes 1 to 4 and 6 was published in 1982, as volume 7, together with the second revision of volume 5. A supplement to Volumes 1 to 4, 6, and 7 was published in 1987, as volume 8, together with the third revision of volume 5. Finally, a supplement to Volumes 1 to 4, 6, 7, and 8 was published in 1992, as volume 9, entitled *Colour Index International Third Edition (Fourth Revision)*, which also incorporated the latest revision of volume 5. Much of the new information had been published in a new series of quarterly *Additions and Amendments* updates from 1971 (Number 1) to, eventually, 2000 (Number 116).

Pigments and Solvent Dyes Edition

For the benefit of the non-textile pigment-using industries, a separate *Pigment and Solvent Dyes* extract, taken from Volumes 2, 3, 4, 5 (second revision), 6, and 7 of the Third Edition of the *Colour Index*, was published in 1982; this extract also included information on *Fluorescent Brighteners* having non-textile uses. A Supplement was published in 1989. An entirely new *Colour Index International Pigments and Solvent Dyes Edition* was published in 1997, followed by a Supplement in 1998. The new edition lists current *Pigments* and *Solvent Dyes* by C.I. Generic Name in hue sequence. Each new-format entry is in tabular form, headed, in most cases, by a structure and its relevant C.I. Constitution Number, together with indications of Hue, Chemical Class, First known product, CAS Number, EU Number, and CPMA Number, as appropriate. Commercial products are then listed, with an opportunity for manufacturers to indicate the physical form and the main uses (paint, plastics, printing inks, and other) for their product. In addition, a sentence can be added to indicate anything special, which may distinguish the manufacturer's product from others under that CIGN. The volume also has a comprehensive alphabetical list of commercial products, including company code letters, physical form, CIGNs, and CICNs.

Heritage Edition

Despite the usefulness of the *Pigments and Solvent Dyes Edition*, it was recognized that the future of the *Colour Index* lay in the eventual publication of a Fourth Edition online. In response to requests for historical information about colorants and their classification, the SDC published the *Colour Index Heritage Edition*, a DVD compilation of all the available information published in the various editions of the *Colour Index* between 1924 and 2000; the DVD contains over 17,500 pages of archive information presented in Portable Document Format (PDF) as scanned page images and was published in 2005.

Current Aspects

The Fourth Edition of the *Colour Index International Online* has continued with the various improvements incorporated into the 1997 *Pigments and Solvent Dyes Edition* [3].

Part 1 covers pigment and solvent dye classes and Part 2 covers dyes and related products. The new format has been devised through consultation with the coloration industry, including manufacturers, users, the Ecological and Toxicological Association of Dyes and Organic Pigments Manufacturers (ETAD), and the Color Pigments Manufacturers Association, Inc. (CPMA). Subscribers can search the online database under various categories, such as CIGN and CICN, chemical class, hue/shade, discoverer, first known product, CAS/EU number, manufacturer name, and commercial product name.

Entries are organized as Fingerprint pages, which aim to include information on C.I. Generic Name, C.I. Constitution Number, chemical structure, chemical class, shade, discoverer, first known product, CAS registry number, EU number, and classical name. Following the Fingerprint entry, commercial information is listed under the headings commercial name, manufacturer, physical form, main uses, and additional product details provided by the company.

Definitions

Revised and agreed definitions have been published on the SDC website as follows.

Essential Colorant(s)

Many commercial products that are placed on the market are not just 100% of the substance responsible for the color. They usually contain, in addition, quantities of other substances (generally referred to as additives) that improve the product's application properties: e.g., its dispersibility, flow, or flocculation resistance. Quite significant amounts of these additives may be present. The essential colorant is a dye or pigment responsible for the color of the product in the absence of additives.

ETAD Definition of Dyes

Dyes are intensely colored or fluorescent organic substances only, which impart color to a substrate by selective absorption of light. They are soluble and/or go through an application process which, at least temporarily, destroys any crystal structure by absorption, solution, mechanical retention, or by ionic or covalent chemical bonds.

CPMA Definition of Pigments

Pigments are colored, black, white, or fluorescent particulate organic or inorganic solids which usually are insoluble in, and essentially physically and chemically unaffected by, the vehicle or substrate in which they are incorporated. They alter appearance by selective absorption and/or by scattering of light. Pigments are usually dispersed in vehicles or substrates for application, as for instance in the manufacture of inks, paints, plastics, or other polymeric materials. Pigments retain a crystal or particulate structure throughout the coloration process.

Definition of C.I. Generic Names (CIGNs)

A C.I. Generic Name describes a commercial product by its recognized usage class, its hue, and a serial number (which reflects the chronological order in which related colorant types have been registered with the Colour Index). This definition enables a particular commercial product to be classified along with other products whose essential colorant is of the same chemical constitution and in which that essential colorant results from a single chemical reaction or series of reactions. The definition also includes multi-

constituent substances but excludes products obtained simply by physical admixture of essential colorants. In some cases, the same essential colorant is present in more than one usage category. Typically, a disperse dye can often be applied as a solvent dye, and a vat dye can sometimes be used as a pigment, e.g., C.I. Pigment Blue 60 and C.I. Vat Blue 4.

Colorants listed under a C.I. Generic Name whose serial number contains a colon differ slightly from those listed under the parent CIGN. This slight difference is usually chemical but may be due to different crystal modifications in the case of certain pigments. Historically, a colon number was added to the serial number of a particular C.I. Generic Name when a new product was reported by a manufacturer as being similar to the original. Similar to can generally be interpreted as slightly different chemically. This imprecise definition gave manufacturers the opportunity to request new C.I. Generic Names for products that should have been given colon numbers. Conversely, subsequent disclosures have sometimes revealed that certain products issued with colon numbers should really have been allocated new CIGNs.

Definition of C.I. Constitution Numbers (CICNs)

In the Third Edition of the Colour Index, each essential colorant disclosed for publication was classified and allocated a separate five-figure C.I. Constitution Number. The original numbering of colorants was in multiples of five so as to leave space for future structurally similar dyes and pigments to be assigned numbers in the correct chemical sequence. From 1997, however, new disclosures have been allocated six-figure C.I. Constitution Numbers (before any additional colon number, where relevant) in order to alleviate the congestion experienced in certain areas, notably monoazo colorants.

Organic Structures

The chemical constitutions depicted in volume 4 (1971) are primitive, uninformative, and

inaccurate; no account is taken of aromaticity, tautomerism, or hydrogen bonding. More realistic structural representations did not appear until the publication of volume 9 (1992). All the chemical structures disclosed in the *Pigments and Solvent Dyes Edition* (1997) were revised and updated [4]. In particular, dominant ketohydrazone tautomers are given for derivatives of phenylazonaphthols and for acetoacetanilide and pyrazolone colorants. Wherever possible, structures are drawn in conformations dictated by the requirements of hydrogen bonding. The positive charge associated with the triarylmethane colorants is located at the central carbon atom for convenience. This publication marked the start of a complete revision of all the structures currently appearing in the online database.

Benzene rings are shown as Kekulé structures. Although the circle in a hexagon notation is a useful shorthand representation of the aromatic sextet in benzene, it is simplistic. Apart from benzene itself, bond type alternation occurs in all its derivatives except for fully symmetrical structures such as hexafluorobenzene. Fusion between a benzene ring and a heterocyclic ring system is always shown at a double bond. For naphthalene, the central bond is always shown as a double bond, in accordance with reality – alternating bond type occurs in naphthalene itself and in all its derivatives. With ketohydrazone structures, the uninvolved ring retains its three double bonds.

The central ring of anthraquinone and its derivatives possesses quinonoid character, so that the Kekulé-type terminal benzene rings are shown as mirror images. As far as possible, a similar approach is used with larger polycyclic quinones.

Azo bonds are never linear. The intermediates used to form azo metal-complex dyes are depicted as hydroxyazo structures.

Use of Colon Numbers

In the Third Edition (1971), the so-called colon numbers were used to subdivide both CIGNs and CIGNs in order to distinguish minor differences in properties or structure, typically between the

variable salts of anionic and cationic dyes or pigments. For example, C.I. Acid Orange 7 (C.I. 15510) is the sodium salt and C.I. Pigment Orange 17 (C.I. 15510:1) is the barium salt. Similarly, C.I. Basic Violet 1 (C.I. 42535) is the chloride salt and C.I. Pigment Violet 3 (C.I. 42535:2) is the phosphotungstomolybdic acid (PTMA) salt.

The use of colon numbers has been extended, somewhat arbitrarily, to include small structural differences, such as ethyl instead of methyl; the adoption of six-figure CIGNs has made it possible to minimize such usage. Improved solubility in nonaqueous solvents can be achieved by forming amine salts of azo metal-complex dyes and, in such cases, a colon number has been added to the CIGN of the parent dye. In a similar manner, solubility in nonaqueous solvents can be achieved with some phthalocyanine derivatives where the same chromophore is involved but the application properties differ considerably. For example, treatment of C.I. Direct Blue 86 (C.I. 74180) with 2-ethyl- *N*-(2-ethylhexyl)-1-hexanamine gives C.I. Solvent Blue 129 (C.I. 74180:2); the barium salt (C.I. 74180:1) is C.I. Pigment Blue 17.

Colon numbers have also been used to distinguish between various crystal modifications and analogues of metal phthalocyanines. For example, C.I. Pigment Blue 15:1 (C.I. 74160), which is reddish-blue, is the α -modification and C.I. Pigment Blue 15:3 (also C.I. 74160), which is greenish-blue, is the β -modification. The only structural difference between C.I. Pigment Blue 15 (C.I. 74160) and C.I. Pigment Blue 75 (C.I. 74160:2) is a change in the central metal atom from copper to cobalt.

Relatively few colon numbers have been issued in the inorganic pigments section of the *Colour Index*. For some extended pigments obtained by a process of coprecipitation, or physical admixture, both the CIGN and the corresponding CIGN have been given a colon number. For example, the cadmium sulfide pigment C.I. Pigment Yellow 37 (C.I. 77199) is coprecipitated or admixed with barium sulfate to form C.I. Pigment Yellow 37:1 (C.I. 77199:1). Other limited usage has been varied and

somewhat inconsistent, and there is no intention of introducing any new colon number usage into the inorganic pigments section.

Product Registration

The allocation of a new C.I. Generic Name for inclusion in the online database is made in response to a specific request from the manufacturer of the new commercial product. As well as providing standard usage information, the manufacturer also has the opportunity to highlight any special features of the product.

In order to minimize the possibility of duplication, the chemical structure of the essential colorant has to be disclosed but will be kept confidential if so desired; for each new product, an appropriate C.I. Constitution Number is allocated.

Combustion Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
Netherlands

Synonyms

[Flame light lamps](#)

Definition

Lamps that produce light as a result of an exothermic reaction between the vapor of a solid, liquid, or gaseous fuel, consisting of hydrocarbons and oxygen.

Types of Combustion Lamps

Torches, oil lamps, candles, and gas lamps all are combustion types of lamps. The light comes from the flame that is the result of a reaction between oxygen and the vapor of a solid fuel in the case of candles, of a liquid fuel in the case of oil lamps, and of a gaseous fuel in the case of gas lamps. A spark is needed for starting the reaction.

Working Principle

In all combustion types of lamps, after a spark has initiated the process, the combustion reaction takes place between the gaseous state of hydrocarbons of the fuel and oxygen from the air. The products of the reaction are carbon dioxide (CO₂), water vapor

Combustion Lamp, Fig. 1 Flame of a candle

(H₂O), heat, and light in the form of a flame. In oil lamps and candles, the wick draws, by its capillary action, the fuel to the flame against the force of gravity. It is not the liquid part of that fuel that takes part in the combustion reaction but the evaporated fuel around the wick. With all combustion lamps, carbon particles of high temperature (soot), resulting from incomplete combustion, are brought to incandescence and contribute to the total light radiation. The blue light at the bottom of the wick (Fig. 1) is the result of the combustion reaction; the yellowish part of the flame is the result of incandescent light from the carbon particles.

The combustion reaction vitiates the atmosphere by consuming oxygen and returning carbon dioxide (CO₂). Non-complete combustion leads to the emission of harmful gasses like carbon monoxide (CO), sulfur oxides (SO_x), and nitrogen oxides (NO_x).

Oil Lamps

Oil lamps represent the oldest form of artificial light. Scraped-out stone oil reservoirs (Fig. 2) with a wick have been in use for lighting purposes since prehistoric times some 20,000 years ago [5, 6]. The basic conception of oil lamps has

Combustion Lamp, Fig. 2 Stone oil lamp found in Lascaux, France, 17000 BC. (Photograph: Sémhur, Creative Commons 3.0 unported)

remained unchanged although the materials used and the type of construction have been advanced quite a bit. The Dutchman Jan van der Heyden, for example, developed in 1663 a closed oil reservoir for street lanterns [7]. He not only made a detailed description of the production process of the oil lamp and lantern but also of the set of maintenance material the lamplighter crew needed (Fig. 3).

The industrial revolution some 200–250 years ago asked for artificial lighting in industrial premises, and in that period a boom in new developments in the technology of oil lamps is seen, followed by developments of entirely new lighting products, such as gas lighting and later electrical lighting. Until the end of the nineteenth century, oil lamps have been in general use, especially for domestic lighting.

Materials and Construction

The Oil

Vegetal or animal oil, rich in carbon, is used. The type was dependent on the availability in the actual region. In warm areas vegetal oil was made from olives, coconuts, and palms and in more moderate climate regions, from colza, linseeds, and rapeseeds. Animal oil was obtained from fish, whale, or domestic animals. Especially sperm whales were hunted and slaughtered for oil obtained from their head cavities. Around 1850 kerosene (also referred to as paraffin oil) was produced from crude oil (also referred to as

Combustion Lamp, Fig. 3 Maintenance set for a lamplighter of oil street lighting installations around the end of the seventeenth century (Drawing van der Heijden 1663, [7])

petroleum) through a refining distillation process. Quickly it became the standard fuel for oil lamps which became known under the names of paraffin, kerosene, or petroleum lamps.

The Wick

In the early oil lamp days, the wick was made from bark, moss, or plant fibers that were twisted together. Later cotton was usually used for wicks. Some oil lamps had multiple wicks, up to 16 in certain Greek and Roman types. Around 1780, experiments with the shape of the wick resulted in a burner that consisted of two concentric tubes between which a tubular wick is located (Fig. 4). Through the open central tube, air is drawn so that the combustion is improved and consequently the light output as well (equally to some ten candles) while reducing smoke and smell. This oil lamp type is named, after its Swiss inventor, the Argand lamp. A further improvement of this type constituted of a glass chimney placed over the flame that increased the upward air draft through the hollow tube (see Fig. 4 again).

The Fuel Reservoir or Lantern

Originally the fuel reservoir was a simple open tray made out of stone, seashell, or earthenware in which the wick was free-floating or laid in a groove in the rim of the tray. Later the reservoir was provided with a nozzle or spout through which the wick was led. Sometimes underneath the spout, a gutter was mounted to catch spilt oil to avoid pollution and for reuse (Fig. 5).

The material used for the reservoir becomes gradually more advanced: brass, copper, silver, pewter, glass, or porcelain. The reservoirs made out of these materials are closed usually with a lid, although with some versions, filling of the reservoir had to be done via the spout. Around 1,800 double-reservoir oil lamps came into use on the initiative of, again, Argand who earlier introduced the double concentric tube burner. These lamps had the advantage that the supply of oil to the wick was relatively constant from a small reservoir that continuously was filled by the force of gravity by a secondary larger reservoir fitted somewhat higher (Fig. 6).

Combustion Lamp, Fig. 4 Argand oil burner with a tubular wick inside a hollow cylinder equipped with a glass chimney [2]

The Carcel lamp had a clockwork that operated a pump to raise the oil to the wick. The light output of the Carcel lamp was so constant that its horizontal intensity was for some time used as the unit of intensity. That one Carcel equals approximately 9.8 cd illustrates the high light output of the Carcel lamp relative to that of a candle. The less complicated “moderator lamp” with a spring-loaded piston to pressure-feed the burner became popular for general lighting purposes. The last improvement in oil lamps dates from around 1900 and in fact comes from technology then already in use for gas lamps. It combines the use of a gas mantle (see a further section

Combustion Lamp, Fig. 5 Brass spout oil lamp with a gutter to catch spilt oil

Combustion Lamp, Fig. 6 Double-reservoir oil lamp

Combustion Lamp, Fig. 7 A modern, double-mantle, pressurized kerosene lantern

“Gas Lamps”) with a hand pump that pressurizes the fuel liquid to force it into the burner for better combustion where its flame brings the mantle to incandescence. The resulting light is brighter and has a cooler color. These types of lamps are still produced today for emergency lighting purposes and for outdoor use (Fig. 7).

Properties

Simple oil lamps have a lumen output of about 10 lumen and a luminous efficacy (based on heat release) of some 0.1 lm/W [1, 3]. The mixture of light from incomplete combustion and incandescence of carbon particles results in a correlated color temperature of approximately 2,000 K [8].

Argand and moderator type of oil lamps have a lumen output in the range of 50–200 lumen

(comparable to 5–25 W incandescent lamp) with an efficacy of 0.1–0.3 lm/W.

Oil lamps equipped with a gas mantle may raise the lumen output to more than 500 lumen with an efficacy of 0.5–1 lm/W (more than 1.5 lm/W for the pressurized types). The correlated color temperature increases to some 2,700 K.

Candles

Candles came in use much later than oil lamps. Spillage of oil and the associated risk of fire have always been a problem with oil lamps. With the invention of the candle made of non-fluid material, the spillage problem was solved albeit not the risk for fire. The candle was less fragile than the oil lamp and therefore more easily portable. The Romans, from the time of the birth of Christ onward, have been responsible for the dissemination of the candle throughout Europe and the Middle East [6]. Today candles are mainly used for devotion and for ambience lighting. Annual retail sales in the USA of candles, today, exceed five billion pieces (calculated based on [1]).

Materials and Construction

The Candle Substance

The first candles were made of hard animal fat (tallow) or of beeswax. Wax candles were of much better quality but also much more expensive. From the end of the eighteenth century, the use of relatively cheap fat from the spermaceti organ in the head of sperm whales improved the quality of candles. Standardized candles on this basis were used as standards for light intensity: the candle-power (only in 1948 the SI unit candela came into use with a value roughly equal to one candle-power). Around 1830 stearin, obtained by chemical treatment of animal or vegetal fat or oil, was added which increased the melting point and consequently reduced dripping of candle fat. Around 1850 candles became much cheaper because of the

use of solid paraffin, a distillation product from crude oil. At that time, however, gas lighting was already, at many places, the source of lighting.

Candles are produced in some different ways:

- By dipping the wick repeatedly in molten candle substance
- By pouring molten candle substance in a glass container
- By pouring molten candle substance in molds
- By drawing soft candle substance through a hole (machinal)

The Wick

The first candles had a wick made of a piece of wood, cord, or animal skin. Around 1800 the braided cotton wick was introduced that reduced the disturbing smoke that accompanied burning candles. The braided wick can have a stiff core, originally made of lead and later of zinc, of paper, or today of synthetic fibers. Most wicks are impregnated with wax to facilitate ignition. Early wicks had to be trimmed regularly. Later wicks got such a structure that they bend, and their residues dip into the molten fuel and are completely consumed so that trimming is not needed.

The Lantern

To reduce the risk of fire but primarily to enable the use of candles outside, candles were used in lanterns made of a perforated metal sheet or with windows of animal horn or glass. Only from the eighteenth century onward, candle lanterns sometimes were equipped with mirrors or lenses to concentrate the light in specific directions.

Monumental buildings and homes of the rich were lit with luxurious candle chandeliers, sometimes decorated with pieces of cut glass that made the light sparkle. In contrast to oil lamps, candles were only for a very limited period used for street lighting.

Properties

The light and color properties of the candle are similar to those of simple oil lamps. The lumen

output of a candle flame is approximately 10 lm and its luminous efficacy 0.1 lm/W [1, 3]. The correlated color temperature is around 1,900 K [8].

Gas Lamps

Oil lamps and candles are light sources where the energy or fuel is stored in the lamp itself. Gas lamps were the first lamps where the energy is distributed to the lamps from a central energy depot at a centralized remote location. The challenge was not only to develop the lamp itself but also the development of town-sized gas production and distribution systems. In 1785, Dutch Jean-Pierre Minckelers demonstrated the use of coal gas to produce light by lighting his lecture room at the University of Leuven with gaslight. The first to make a public demonstration of gas lighting was the Scot William Murdoch when he in 1802 installed a gas pipe network with gas burners for the lighting of the facades of a range of buildings of James Watt's Soho Factory in Birmingham [3, 5, 6]. Oil and candle lighting was quickly replaced by gas lighting, first in street lighting and industrial premises, quickly followed in indoor areas of the rich. In 1875 the new Paris Opera got some 45 km of gas pipe with 960 gaslights connected to it.

With the introduction of electric incandescent lamps in 1880, some 75 years after the first use of gas lighting, the use of gas lighting decreased quickly. Even today, however, in some cities in the Western world, gas lighting for street lighting is still in use. The city of Berlin, for example, uses some 40,000 gas lanterns.

Materials and Construction

The Gas

Gas for lighting was sometimes produced by heating animal fats or vegetal oil but mostly by heating coal. When the latter is done in an air-free atmosphere, in cast-iron retorts, the percentage of methane in the gas is higher, resulting in better combustion and therefore in more light. After its

Combustion Lamp, Fig. 8 Bicycle carbide lantern working on acetylene gas

original application, this type of gas was named “illuminating gas.” Illuminating gas produces a whiter light than the blue light of natural gas (only after the invention of the gas mantle – see next section – also natural gas could be used for gaslights). The gas was stored in huge gas storage tanks or gasometers, in some cities preserved as historic landmarks.

A special kind of gas was used for carbide gas lamps on bicycles and early automobiles: acetylene gas obtained by dripping water from a small reservoir in another reservoir under it that contains calcium carbide (Fig. 8).

The Burner

Open Flame Burner The first burners, so-called open flame burners, were merely a hole or a series of holes at the end of a pipe. The double concentric tube burner with a glass chimney, as used since the end of the eighteenth century by Argand for his oil burners, was often used for open flame gas burners as well. It was realized that the higher the temperature of the flame, the larger the lumen output of the flame would be. In 1858 William Sugg, therefore, introduced burners made from

non-heat-conducting steatite that became hotter than heat-conducting metal burners.

Gas Mantle Already in 1825, it was known that by putting solid material into the flame, this material could be brought to incandescence. In this way, both the light output and color of the flame could be influenced. A piece of lime from limestone brought into the flame resulted in an extremely intense and compact light source that was used as a spotlight in theaters (Fig. 9). The expression “in the limelight” originates from this.

In 1885 the Austrian Carl Auer von Welsbach succeeded in using a knitted mantle of solid material around the gas flame (Fig. 10). The material consists of a pear-shaped net of fabric impregnated with the nitrates of the rare-earth metals thorium and cerium. After drying, the fabric is burned off and what remains is a fragile, inflammable structure: the gas mantle existing of the oxides of thorium and cerium that is brought to incandescence in the gas burner. Because of its fragility, the mantle has to be replaced regularly.

The gas mantle improved both the light output and efficacy of gas lamps considerably because thorium and cerium oxides produce more light in the visible spectrum range than a black body at the same temperature does (selective radiation). The gas mantle invention has stretched the actual use of gas lighting well into the era of the first 50 years of electrical lighting.

Regenerative Burners Around 1880 the so-called regenerative gaslight systems further improved the efficiency of gas lamp systems. The heated air produced by the flame is guided such that it preheats the incoming air needed for combustion. Often this principle was applied with inverted gas mantle burners in which the heat of the flame is better retained in the mantle.

The Lantern

The design of the early gas lanterns was very much based on the design of oil lanterns of that period.

Combustion Lamp,

Fig. 9 From top to bottom: limelight gas burner with a piece of limestone, a box with limestones, theater spotlight projector in which the limelight gas burner is fitted. (Photographs: Stage Lighting Museum, Israel, creator Dan Redler)

Chandeliers for gas lighting were equipped with pull chains for switching the gas supply on and off and to control, through the quantity of gas supply, the light output. They also often had thin secondary gas pipes connected to the so-called pilot lights that were always on so as to enable the main gaslights to be ignited without the use of matches (Fig. 11).

Lanterns for gaslights with gas mantle always had a glass cover to protect the fragile mantle and to restrict glare. The glass cover, of course, was open at the bottom to permit inlet of air needed for

combustion. The top part of the lantern had a ventilation shaft working as a chimney (Fig. 12). Most lanterns for use in street lighting and for the lighting of industrial premises had multiple gas mantle burners varying in number from 2 to more than 10.

Ignition Control

In large part of the nineteenth century, gas street lighting lanterns were ignited each day at dusk by a patrolling lamplighter (Fig. 13). With a stick on

which a torch was fitted, he opened a trap door in the bottom of the lantern, opened the gas valve with a hook on the stick, and ignited the flame with the torch.

Later, gas lanterns had for remote ignition a pilot lamp connected through a bypass to the main gas pipe. Gas supply was remotely controlled by

gas valves actuated by gas pressure or by a mechanical clockwork built into the lantern. From 1900 onward remote gas igniters came on the market which did not need a pilot light. A platinum sponge, existing of a porous mass of finely divided platinum, initiates a flame by catalytically combining oxygen with hydrogen from the gas when the gas valve is opened. Later, also battery-operated remote igniters came into use.

Properties

A single gas burner without mantle has a lumen output of 10–50 lumen with an efficacy of 0.2–0.5 lm/W [1, 3]. The spectrum of radiation depends on the type of gas and the oxygen supply that together determine the quality of the combustion reaction and the soot particles that take part in the incandescence process. Figure 14 shows different colored gas flames resulting from different types of gas and different oxygen supply. Open flame burners on “illuminating” gas have the color of flame as shown on the left: yellowish white light from incomplete combustion and incandescence of soot particles. Modern gas ovens have

Combustion Lamp, Fig. 10 Gas mantle

flames as illustrated on the right: a blue flame from complete combustion, without soot particles taking part in the process. The correlated color temperature of the open burner gas flame, burning on illuminating gas, lays around 2,400 K [4].

Gas burners with a gas mantle have per mantle a lumen output of 200–600 lumen (comparable to that of a 25–60 W incandescent lamp) at 1–2 lm/W [1, 3, 8]. It is interesting to compare this luminous efficacy with that of Edison's first incandescent bulb: 1.4 lm/W. The correlated color temperature is dependent on the composition of the mantle.

Typical values are 2,700–2,900 K [4]. The lifetime of a gas mantle was some 50–200 h. Modern gas mantles, as used today in professional street lighting lanterns, have a life of up to 4,000 h.

The effect of the main pressure on the performance of gas lamps was much less than the effect of main voltage on the performance of most electric lamps. From the last quarter of the nineteenth century, most gas lanterns are equipped with a small pressure governor that keeps the outlet pressure within acceptable limits.

Complementary Colors

Paul Green-Armytage
School of Media, Creative Arts and Social
Enquiry, Curtin University, Perth, Australia

Synonyms

[Contrary colors](#); [Contrasting colors](#)

Definition

Complementary colors are colors that “complete” each other. This completion can be understood in terms of some physical relationship or in terms of how the colors are related in their appearance. There are different ways of establishing these relationships, two being widely accepted: By one definition, two paints, inks, or colored lights are complementary if their mixture can yield a neutral black, gray, or white. This is a physical

relationship that can be demonstrated. By another definition, two colors are complementary if the afterimage of one color has the same hue as the other color. This is a phenomenal relationship that can also be demonstrated. It is also common simply to claim that colors opposite to each other on a color circle are complementary, without further explanation or justification. Complementary relationships can be helpful when mixing paints to produce particular results. Complementary relationships also feature in theories of color harmony.

Introduction

The notion of complementary colors is caught between science and art, between what can be measured and what cannot. But this notion can also be seen as a bridge. If there are objective ways of establishing complementary color pairs, and if such pairs are found to be pleasing, then complementary colors may be a key to color harmony – harmony could be subject to measurement. One difficulty here is that different ways of establishing complementary relationships do not yield exactly the same results. A number of these ways are described and illustrated in the sections that follow. There is also the problem of what comes first, the objective methods or the experience of harmony. The idea that some color pairs are more pleasing than others is older than any demonstration of particular physical or phenomenal relationships of the kind associated with complementary colors. Perhaps the earlier judgments are endorsed by the later demonstrations, or perhaps the demonstrations show color relationships that are now widely agreed to be harmonious.

Color Harmony

Harmony is a slippery word. Most definitions deal with harmony in music, but there it has more than one meaning. It can mean a combination of notes which have a pleasing effect [1]. It can also mean a combination of notes organized according to a system of structural principles [2]. The same definitions could be applied to color combinations. According to the first definition, only those color combinations

that are found to be pleasing are harmonious. This could make color harmony a private matter; harmony, like beauty, would be in the ears of the listener or the eyes of the beholder. Only some kind of consensus could establish a wider claim for some color combinations to be accepted as more harmonious than others. Whether the judgment is made by an individual or a group, this definition depends on evaluation. With the second definition, there are also limitations. Only with certain relationships between notes and colors can a combination be called harmonious. The relationships can be measured, so the definition depends on description. Philosophers might argue about the possibility or impossibility of any link between description and evaluation, but for most people, to say that there is an interval of a third between the notes C and E when they are sounded together in a chord is description, while to say that the chord is pleasing is evaluation. Similarly, to give Munsell or Natural Color System (NCS) notations for the two colors in a particular combination is description, while to say that the combination is beautiful is evaluation. The idea of a link between description and evaluation as the basis for some theories of color harmony is discussed in a paper that was presented at a conference in Gothenburg in 1996 [3].

Pleasing Color Combinations

Before the invention of the color circle, or any notion of a special relationship between colors that are opposite to each other on a circle, there was a recognition that certain color pairings are more satisfying than others. Leon Battista Alberti, in fifteenth-century Italy, claimed that “there is a kind of sympathy among colours whereby their grace and beauty is increased when they are placed side by side. If red stands between blue and green, it somehow enhances their beauty as well as its own” [4, p. 85]. Leonardo da Vinci introduced the notion of “contrary colors” and suggested that pairs of contrary colors enhance one another. “The colours which go well together are green with red or purple or mauve, and yellow with blue” [5, p. 73]. Martin Kemp points out that “this account of colours which ‘go well together’

comes close to the doctrine of ‘complementary colours’ as defined in the eighteenth and nineteenth centuries, but lacks the systematic base provided by the later colour wheels” [6, p. 284].

To find out whether people might intuitively choose particular colors as going well together, without appeal to a color wheel or any theories of complementary colors, a preliminary investigation was carried out at Curtin University of Technology in 1994. Students worked with colors of equal nuance from the Natural Color System (NCS). Each was assigned a particular color and asked to find a color to go with it so that the combination would be the most beautiful, most exciting, or most harmonious. The intention was to go back to the kind of judgments made by Alberti and Leonardo, to find colors that were most “sympathetic” or “contrary.” Students generally agreed on which color pairings were the most “beautiful” and the most “exciting”, but there were two schools of thought about what kind of color relationship is “harmonious” – colors of similar or contrasting hue. And it was not always the same colors that were selected as contrasting. There was a small range comparable to the “red or purple, or mauve” as nominated by Leonardo for “going well” with green. A more rigorous study, with a larger number of participants, might lead to firmer conclusions. But it does not seem likely that an approach, from this direction, to the identification of complementary colors would yield precise results. The “complementary” of a given hue would not be a single hue but a narrow range of similar hues. This can be set beside the imprecise results when the approach is from the other direction, starting with the theories.

Ways of Establishing Complementary Colors

With different ways of establishing complementary relationships yielding different pairs, no color can be said to have a single complementary hue unless a decision is first made about which way of establishing complementary relationships is “correct.”

Colored Shadows

In one of his diagrams, Leonardo da Vinci illustrates a spherical body (a) being lit by two lights (d) and (e). Two shadows are cast (b) and (c). He explains that “the shadow formed by the light *e*, which is yellow, will tend towards blue, because the shadow of the body *a* is formed on the floor at *b*, where it is exposed to the blue light, and accordingly the shadow made by the light *d*, which is blue, will be yellow at the location *c*, because it is exposed to the yellow light” [5, p. 74].

Later observers noticed that a blue shadow would be cast by a yellow light even if another light, shining on the shadowed area, was not blue but white. A systematic study of colored shadows was carried out by Count Rumford who reported his results to the Royal Society of London in 1794. Rumford concluded that the phenomenon was subjective. He went further and suggested that his results might serve as a guide to artists in “the magic of coloring,” and he introduced what was then a new term: “one shadow may with propriety be said to be the *complement* of the other” [7, p. 295]. Moses Harris, in 1766, also describes the colored shadow phenomenon and points out how the colors of the light and the shadow are opposite to each other on his color circle [8, p. 8]. Johann von Goethe explains how to conduct the colored shadow experiment with a candle and the full moon as light sources. And he has a beautiful account of how he experienced a sequence of colored shadows on a walk in the Harz Mountains. The ground and trees were covered in snow and hoar frost. Toward the end of the day, the shadows cast by the trees were “decidedly blue, as the illumined parts exhibited a yellow deepening to orange.” Then, as the sun began to set, it “began to diffuse a beautiful red colour over the whole scene around me, the shadow colour changed to a green, in lightness to be compared to a sea-green, in beauty to the green of the emerald. The appearance became more and more vivid: one might have imagined oneself in a fairy world, for every object had clothed itself in the two vivid and so beautifully harmonising colours” [9, pp. 34–35]. Colored shadows may be a subjective phenomenon, but it is possible to record them in photographs, as shown in Fig. 1.

Complementary Colors, Fig. 1 Demonstration of complementary colors as seen in colored shadows. At top left the candlestick is lit by two white lights and casts gray shadows. In the other photographs, colored filters were

placed in front of the light shining from the right while neutral filters were placed in front of the other light to equalize the illumination. The shadow colors can be described as being complementary

Afterimages

Colored shadows may be linked to the experience of afterimages. Martin Kemp identifies the Comte de Buffon as “the pioneer in the study of subjective colour.” Buffon described colored shadows and also afterimages at the French Academy of Sciences in 1742–1743 [7, pp. 294–295]. Afterimages were introduced by Moses Harris when he explains how the world will look if green-tinted spectacles are worn for about 5 min and then removed: “every scene and object will look of a fiery red, opposite to green you will find red” [8, p. 8]. In the Harris color circle, colored shadow and afterimage color pairs are to be found opposite to each other. For Goethe, afterimages were the key to color harmony. He saw, in the experience of an afterimage, the eye’s search for completeness, and he concludes that “in this resides

the fundamental law of all harmony of colours” [9, p. 317]. Goethe had only six colors in his color circle so, within each segment, there could be a range of different hues under the same name. Red would range from orange red to purple red and in that range the afterimage for a particular green might be found. If more precise identification of afterimage hues is required, there are two questions to be considered: If a particular red is the afterimage of a particular green, does it follow that the same green will be the afterimage of that red? Is the afterimage phenomenon reciprocal in this way? The second question takes account of afterimages as subjective experiences peculiar to the individual. So is it possible to know whether everyone experiences the same hue as the afterimage of a given color?

Afterimage Color Progression

The assumption that two colors could be each other's afterimage was investigated by Nathan Cabot Hale. Cabot Hale claimed to have found what he called "after-image color progression" [10, p. 262]. Having experienced a yellow as the afterimage of a blue, he found that the afterimage of the yellow was a violet. Then the afterimage of the violet was a green and this progression continued right round the circle. Cabot Hale's claim was investigated, in turn, by Western Australian artist Sally Douglas. Douglas did not find such strong hue shifts as those reported by Cabot Hale, but she did find progression all round the circle. Her method and results are shown in Fig. 2.

Having painted a patch of reddish orange, Douglas stared at it, looked away, and matched its afterimage which she saw as a pale turquoise. She then increased the intensity of the turquoise, being careful to retain its hue, and repeated the process for the turquoise. The afterimage of the turquoise was slightly more yellowish than the

original reddish orange. In a carefully controlled operation, where such color relationships were established in random order, she found, when she put it all together, a progression right round the circle.

Individual Variations in the Experience of Afterimages

To see if individuals have the same afterimage experiences from given colors, students at Curtin University of Technology were assigned specific paints and asked to match the colors they experienced as the afterimages. Some of the results are shown in Fig. 3.

The slight variations in hue may be due to inaccurate mixing but studies by Marian-Ortolf Bagley have confirmed that there are, indeed, variations in how individuals experience afterimages [11]. Rather than have the participants in her study match the afterimages in paint, she asked them to identify their afterimage colors from the samples in the Munsell book of color.

Complementary Colors, Fig. 2 Afterimage color progression as recorded from her observations by Sally Douglas

Complementary Colors, Fig. 3 Afterimage colors as recorded by individual students at Curtin University of Technology

Colors That Are Least Like Each Other

Wilhelm Ostwald points out how “if one moves away from a given hue in the hue circle, the colors become increasingly dissimilar” [12, p. 33]. Since the hue circle is continuous, there will come a point where this dissimilarity is at its greatest, and beyond which there will be a progressive return to similarity. For Ostwald, “there exists for every hue in the hue circle another that is most different from it. This relationship is mutual. The entire hue circle is filled with such pairs of contrasting colors, which shall be called complementary colors” [12, p. 34]. However, the determination of least similarity must depend on the judgment of observers, and such judgments are likely to vary. Ostwald preferred precision. Accordingly he appeals to mixture and proposes an alternative definition: “Complementary colors are colors which in an optical mixture yield a neutral gray” [12, p. 35].

Mixture to a Neutral

When discussing mixture, it is important to distinguish between the paints, inks, or lights that are being mixed, on the one hand, and the appearance of those paints, inks, or lights and the resultant mixture, on the other hand. If a paint that appears

red is mixed with a paint that appears blue, the mixture will appear purple, more bluish, or more reddish depending on how much of each paint is in the mixture. There are different ways of mixing: subtractive, additive, and partitive. The results of one way of mixing are not always a guide to the likely results of the other ways.

Subtractive Mixture

Subtractive mixture occurs when paints are mixed in the palette, when inks are premixed before being used on the press, and when transparent inks or paints are applied in layers one over the other. Subtractive mixture also occurs when two differently colored filters are placed in front of a single light source. Experiment with different paint combinations can lead to the discovery of a pair of paints that can be mixed to a dark gray as shown in Fig. 4.

Moses Harris claims that if such colors (i.e., paints) are mixed and are “possest of all their powers, they then compose a deep black” [8, p. 7]. But he concedes that no pigments that are generally available, like those used for Fig. 4, have such “powers.” Instead of deep black, the result here is a neutral dark gray.

Complementary Colors, Fig. 4 Dark gray in the middle of a sequence of colors mixed from varying amounts of two paints which appear blue and orange when used straight from the tube

Complementary Colors, Fig. 5 Similar colors in filtered lights and on painted paper discs can mix additively and partitively to a neutral – white or gray

Additive and Partitive Mixture

Additive mixture occurs when beams projected from two filtered light sources overlap on a screen. Partitive mixture occurs when a disc with segments painted in different colors is spun at high speed. The results of additive and partitive mixture are shown in Fig. 5.

Partitive mixture was the method used by Ostwald to establish complementary pairs which he then placed opposite to each other on his circle. Ostwald's circle has yellow opposite blue, as in Fig. 5, where Harris has orange as in Fig. 4.

Possibilities from Physics

In the introduction to his book *The Principles of Harmony and Contrast of Colors and Their Application to the Arts*, Michel-Eugène Chevreul suggests a precise definition: “if we re-united the total quantity of the coloured light *absorbed* by a coloured body, to the total quantity of coloured light *reflected* by it, we should reproduce white light: for it is this relation that two differently coloured lights, taken in given proportions, have of reproducing white light, that we express by the terms *Coloured lights complementary to each*

other, or complementary colours” [13, p. 54]. From this, one can imagine a spectral reflectance curve which would serve as a kind of template for a second curve – where one curve had peaks, the other would have valleys. This may be a theoretical ideal; it is doubtful whether two surfaces could be found with such perfectly matched reflectance curves.

Newton's Rings

Color relationships that could be regarded as complementary can be seen in a close examination of Newton's rings. Isaac Newton describes the phenomenon that bears his name in his book *Opticks*. He found that “By looking through . . . contiguous object glasses . . . that the interjacent air exhibited rings of colours, as well by transmitting light as by reflecting it. . . Comparing the coloured rings made by reflection, with those made by transmission . . . I found that white was opposed to black, red to blue, yellow to violet and green to a compound of red and violet” [14, book 2, part I, observ. 9].

Polarized Light and Cellophane Tape

Polarized light can also reveal striking color contrasts when cellophane tape is sandwiched

Complementary Colors, Fig. 6 Colors revealed when cellophane tape is sandwiched between two polarizing filters. The axes of the filters are parallel on the left, at 45° in the center, and at 90° on the right

between two polarizing filters. The filters only transmit light that is vibrating in one plane which means that each filter has what might be called an axis. When two filters are superimposed, they will transmit more or less light depending on the relationship between the axes. If the axes are at right angles to each other, no light is transmitted. The cellophane tape has the effect of modifying the light as it passes through so that certain wavelengths, visible as colors, are transmitted even when the axes are at right angles. This is demonstrated in Fig. 6.

The colors that are seen in the stripes depend on the relationship between the axes and on how many layers of tape there are – in this case, one, two, and three layers, the three-layer stripes being the ones in the center. The colors change radically as one filter is rotated in relation to the other. The colors on the left in Fig. 6 could be described as being complementary to those in the corresponding positions on the right. A more detailed, but simple, explanation of this effect is provided for the “Polarized Light Mosaic” which is included in the *Science Snackbook* compiled by the Exploratorium Teacher Institute [15, p. 78].

Contradictory Complementaries

It is clear from the above that there is no single complementary color for each hue in the color circle. A study to establish complementaries by different definitions was carried out in 1981.

Gouache paints, manufactured by Winsor and Newton (WN) and Pelikan (P), were used for this study. The results are illustrated in Fig. 7.

While carrying out the study, it was assumed that two colors can be each other’s afterimage. Given the findings of Sally Douglas, shown above in Fig. 2, such a color circle cannot be constructed except to suggest that opposite colors are close to being each other’s afterimage. The afterimage of unique blue may be a yellow orange, but the afterimage of that yellow orange may be a blue that is very slightly reddish.

An Elastic Color Circle

The issue of contradictory complementaries is discussed in the entry on the color circle in this encyclopedia. An elastic color circle is proposed as a way of illustrating how the number of steps between the unique hues would need to be increased or decreased to bring differently defined complementary pairs opposite to each other. The illustration from the color circle entry is repeated here as Fig. 8.

Complementary Colors as a Guide to Mixing

Complementary colors can be used as a guide to mixing paints, inks, or lights. Given that the results of subtractive and additive/partitive mixture are not the same, the elastic color circle can help to clarify the situation. Figure 9 shows an

Complementary Colors, Fig. 7 Chart showing the results of a study to find complementary color pairs (partners) according to different definitions

extreme example of the way in which the same two paints can be used to produce radically different results from subtractive and partitive mixture. Here the blue and the yellow are more reddish than the blue and yellow in Fig. 5. The result of subtractive mixture is a dull green, but on the spinning disc, the result is a dull pink.

Lines connecting that blue and yellow pass through green on the subtractive circle, but through pink (red) on the additive/partitive circle, as shown in Fig. 10.

Painters are often advised to use complementary colors, rather than black, white, or gray, to modify the appearance of colors in their painting

Complementary Colors, Fig. 8 Color circles based on subtractive mixture complementaries (left), afterimage complementaries (center), and additive mixture complementaries (right). The color circles illustrated here were developed from the results of the study shown above in Fig. 7

Complementary Colors, Fig. 9 The same two paints mix subtractively to a dull green and partitively to dull pink

Complementary Colors, Fig. 10 Dotted lines trace the possible results from subtractive (left) and additive/partitive mixtures (right) of a reddish blue and a reddish yellow

that they feel are too vivid. Black, white, and gray paints are felt to have a deadening effect.

Complementary Colors as a Guide to Color Harmony

Complementary colors underpin many theories of color harmony, notably the theories of

Johannes Itten, author of what may still be the most influential and widely used books on color theory for students of art and design today [16, 17]. Itten argues that “the concept of color harmony should be removed from the realm of subjective attitude into that of objective principle” [17, p. 19]. He is unequivocal when he claims that “we can make the general statement that all complementary pairs ... are harmonious” [17,

p. 21]. And he supports this claim by offering three objective means of establishing complementary relationships: “the after-image always turns out to be of the complementary color . . . colors (lights) are harmonious if they mix to give white . . . colors (paints or pigments) are . . . harmonious if their mixture yields a neutral gray” [17, pp. 19–20]. These three definitions cannot coexist in a single color circle. There would need to be separate circles, one for each definition, if complementary colors are to be opposite to one another, and that would mean three possible frameworks for harmonious color combinations. If blue is to be one of the colors in a harmonious two-color combination, the other color would be orange, orange yellow, or yellow, depending on which circle was used. These combinations are shown in Fig. 11.

According to Itten, any regular geometric figure can be placed inside the color circle, and its vertices will connect with colors that will form a harmonious combination. An equilateral triangle can be used to find three-color combinations, or triads. Again, with blue as a constant, three rather different combinations would be found in the three circles. These are shown in Fig. 12.

Choosing a Single Definition as the Key to Harmony

Robert Hirschler discusses the potential for confusion arising from different ways of defining complementary colors. Hirschler quotes David MacAdam who was concerned with problems of measurement: “only that definition which states that the optically additive mixture of two complementary colors must match some arbitrarily assigned ‘neutral’ stimulus is sufficiently specific” [18, p. 1]. This way of establishing complementaries appealed to Ostwald and he used it as the basis for his theories of color harmony. And it is certainly true that optical mixture with spinning discs (partitive mixture) was the easiest way to establish precise complementary relationships during the study described above. A large range of vivid and consistent colors can be produced when gouache paints are used straight from the tube. Paper discs were painted and interleaved in very many combinations of two. The proportions were adjusted until particular combinations in particular proportions were found which would spin to appear neutral gray. These are illustrated in Fig. 7. However, it does not follow that the degree of precision obtainable with this process means that this must be the only “correct” way of establishing complementary color pairs which would be, by definition,

Complementary Colors, Fig. 11 Blue with three different complementary colors for three different definitions: (left to right) subtractive mixture, afterimages, and additive/partitive mixture

Complementary Colors, Fig. 12 Blue as one of three colors in combinations found by an equilateral triangle placed inside each of three color circles where

complementaries are established by, from left to right, subtractive mixture, afterimages, and additive/partitive mixture

harmonious. For Goethe, the key to harmony was afterimages, “a natural phenomenon immediately applicable to aesthetic purposes” [9, p. 320]. Afterimages, as subjective experiences, are not so easy to measure but they involve the observer more intimately, and the experience of an afterimage suggests that the visual system is seeking some form of completeness. Chevreul imagined two spectral reflectance curves which would produce white light when combined. A color stimulus and its afterimage could be the perceptual equivalent.

Complementary Colors as a Fuzzy Concept

Artists and designers, who are looking for some formula that will lead to harmonious color combinations, may be perplexed to find that the color circle is unstable as it adjusts to comply with different definitions of complementary colors. Rather than worry about which definition, and its corresponding color circle, is “correct,” it might be more fruitful to accept complementary colors as a fuzzy concept and make decisions based on personal judgment. After studying the color combinations illustrated in Figs. 11 and 12, a choice can be made. If one combination seems more satisfying and harmonious than the other two, the corresponding color circle could be adopted and Itten’s ideas applied. This could give the artist or designer a feeling of ownership while still providing a sense of security with a clear framework for developing harmonious color combinations. Alternatively, a more flexible approach could be taken. If information about the likely results of mixing is needed, then reference could be made to the subtractive or additive circles as appropriate. But as a framework for developing harmonious color combinations, the color circle could be regarded as offering a choice within limits. While a given color may have more than one complementary, as different definitions are applied, those complementary colors will not be radically different in hue. Even in the most extreme example illustrated here, the alternative complementaries for blue, there is not a large spread between yellow and orange. This range can be considered as offering a choice with the

decision being left to the judgment of the artist or designer. It is worth noting that Alberti and Leonardo both nominated more than one color as being “sympathetic” or “contrary.” Alberti mentions red in relation to blue and green and Leonardo lists red or purple or mauve as going well with green.

This more flexible attitude to the color circle is recommended by Deryck Healey. Having introduced a 12-hue color circle based on subtractive mixture, with the printers’ cyan, magenta, and yellow as primaries (the so-called process inks), Healey illustrates combinations that deviate somewhat from strict adherence to Itten’s rules. He advises the reader to “study these examples of harmony and contrast. Few are strictly precise triads, split complementaries and so on; rather they illustrate how such themes may be subtly interpreted and still retain the desired characteristics of their general category” [19, p. 40].

Conclusion

Complementary colors, as defined by mixture to a neutral or by afterimages, provide reference points for the relationships between hues in a color circle. When the relative positions of hues are determined by mixture, the different results from subtractive and additive/partitive mixtures can be recognized and the appropriate circle used as a guide. More problematic is the role of complementary colors in theories of color harmony. Different definitions lead to different relationships between the hues in the color circle. This could lead one to question the theories or abandon them altogether. Nevertheless, the theories are interesting and can be helpful, especially for those who lack confidence in their own intuition. If a choice has to be made between the different circles, there are arguments in favor of objectivity and subjectivity. On the side of objectivity, there is the circle based on additive/partitive mixture where the color pairs are most readily measurable. This has the support of MacAdam and Ostwald. On the side of subjectivity is the circle based on afterimages which relates more directly to the personal experience of color and the judgments of beauty and harmony as made by the observer.

This has the support of Goethe. In the end, it is up to the artist or designer to choose a single circle or to take a more flexible approach as recommended by Healey. An advantage of the elastic color circle is that it allows one to stretch the rules without breaking them.

Definition

Compositing is the act of combining two images or video sequences, producing a new image or video sequence. There are several techniques to composite two images (or video frames): alpha matte, gradient-domain blending, deep compositing, multiply, overlay and screen modes, etc.

Chroma keying is the name of one of such techniques which uses color hues (chroma) to guide the compositing process. A portion of the

target image is selected (based on a color or a range of colors) and substituted by the image to be inserted. This technique is widely adopted in video editing and postproduction.

Origin of the Terms

Traditionally, both in TV and films, there have been four basic compositing techniques: matting, physical compositing, background projection, and multiple exposure.

- **Matting** is currently the most widespread technique and corresponds to the general definition given above. Digital compositing relies entirely on variations of this technique: *chroma keying* is an example of matting.
- **Physical compositing**: When capturing the background image, an object is physically introduced into the scene to be composited as foreground image. For instance, a *glass shot* consists of recording a scene through a transparent glass where some elements (or most of it) are painted on the glass (some background buildings, for instance). The area of the frame where the action happens is left clear.

- **Multiple exposure**: One of the earliest compositing techniques ever developed, achieved by recording multiple times with the same film, but exposing a different part each time with the help of a mask over the lens. Georges Méliès, pioneer of visual effects, used it to obtain multiple copies of himself in the film the *One-man band* (Fig. 1).
- **Background projection**: This technique, currently fallen in disuse, is based on projecting the desired video or image onto a background screen with the foreground elements (actors, objects) between the camera and this screen. The development of digital compositing and its own complexities (synchronization issues, illumination constraints) rendered this method obsolete.

Techniques

This section describes some of the standard techniques in image compositing together with the latest advances in the last decade. For further exploration of digital compositing, visual effects, and specific examples in the film industry, please refer to the work of Ron Brinkmann [1].

Compositing and Chroma Keying,

Fig. 1 One of the first examples of compositing in films. A frame from George Méliès *One-man band* movie (1900)

Chroma Keying

This method renders a range of colors in the foreground image as transparent, revealing the image below. Blue and green are the most used color in films, videogames, and TV due to their hue distance from the human skin tone. The main disadvantage of chroma keying is that it requires a lighting set with a (sometimes rather large) chroma screen which has to be as evenly illuminated as possible in order to minimize the range of color variations (noise) in the background (Fig. 2). A secondary issue is that the object (or person) to be inserted cannot have any of the hue values used for chroma keying (e.g., a green dress).

Green is generally preferred over blue due to the lower energy required to produce an even illumination over the chroma screen. However, sometimes blue is used whenever there is a risk of green tones appearing in the foreground layer (e.g., outdoor scenes with vegetation which produce green interreflections). In computer graphics, chroma keying is usually obtained as a function of RGB values which measures the differences from the range of colors used for chroma keying (which is analogous to finding the distance to a closed 3D surface in space color):

$$\begin{aligned}\alpha(p) &= f(R_0, G_0, B_0) \\ &= d(R_0, R_{ck}) + d(G_0, G_{ck}) + d(B_0, B_{ck})\end{aligned}$$

where d is a distance function (e.g., *Euclidean distance*) and both (R_0, G_0, B_0) and (R_{ck}, G_{ck}, B_{ck}) are the red, green, and blue channel values, respectively, of pixel p in the image and the color used for chroma keying.

Alpha Blending

Compositing is based on the information stored in the alpha channel of the inserted image. Introduced for the first time in the image editor *Paint3* in 1970, the *alpha channel* [2, 3] stores a value between 0 and 1, 0 being a pixel which is completely transparent and 1 completely opaque. This channel in a 2D image is a grayscale image by itself called *matte*, which can be visualized and edited. Multiple file formats support alpha-extended data (like RGBA): PNG, TIFF, TGA, SGV, and OpenEXR.

Although binary alpha masking (exclusively 0 or 1) is generally suitable for several compositing scenarios, complex visual phenomena such as transparency or translucency require a subtle gradation of alpha values (e.g., separating a dog from its background requires dealing with strands of hair which capture and scatter the environment light).

Still an open problem, researchers have developed complex methods to obtain these subtle matte masks with the minimal user input. For instance, Levin et al. [4] propose a method called *spectral matting*, which finds clusters of pixels

Compositing and Chroma Keying,

Fig. 2 Example of chroma key compositing (*green screen*). The actress is overlaid with a synthetic background in real time on camera. (Source: Deviantart artist: AngryDogDesigns)

with affinity properties (such as X, Y, and/or RGB distances) by relying on spectral analysis (with matte Laplacian) to evaluate automatically the quality of a matte without explicitly estimating the foreground and background colors. This method requires less user input than most approaches (four strokes on average) in order to distinguish the foreground from the background.

Blend Modes

The majority of the image compositing software includes multiple blending modes, that is, different functions to mix each pair of pixels from two overlaid images depending on their RGB values and the layering order. There are several well-known modes [5]: multiply, screen, overlay, soft light, hard light, dissolve, color dodge, addition, subtraction, darken, lighten, etc. Some of them might differ in implementation and formulation, but some of the most established and agreed modes are described here:

- **Multiply:** Both pixel values are multiplied. The result tends to be darker than any of the original images: dark (black) values are preserved, while white values have no effect in the final composition. This mode is especially useful when combining black and white line drawings with color images.
- **Screen:** Considered as the opposite of the previous mode. Both layers are inverted and multiplied. The final result is inverted again. It tends to produce brighter images than the original, as bright values are preserved and black pixels have no effect. If a denotes the

background pixel and b the foreground pixel, the following equation shows how the screen blend mode is applied:

$$f(a, b) = 1 - (1 - a)(1 - b)$$

- **Overlay:** A hybrid mode based on a combination of multiply and screen modes, guided by the value of the background layer. Foreground colors overlay the background while preserving its highlights and shadows:

$$f(a, b) = \begin{cases} 2ab & \forall a \leq 0.5 \\ 1 - 2(1 - a)(1 - b) & \forall a > 0.5 \end{cases}$$

Gradient-Domain Compositing

Gradient-domain techniques aim to merge two images, making the boundary between them imperceptible. They rely on image gradients (differences of pixel values instead of absolute values), looking for the composite that would produce the smoothest fuse of the gradient field (see Fig. 3). These approaches were introduced by Perez et al. in 2003 [6], being now the standard in commercial software (like the *healing brush tool* in Adobe Photoshop).

The latest research advances combine gradient domain with multi-scale methods and visual transfer to produce compositions which mimic even the structural noise at different spatial levels [7].

Deep Compositing

Deep compositing techniques, in addition to the usual color and opacity channels, take into account depth information stored at each pixel along the

Compositing and Chroma Keying, Fig. 3 Example of image compositing based on gradient domain and proximity matching (Photoshop). An area from the input image (left) is selected with a loose stroke (middle), from which a

radius is derived to analyze gradient and color affinity. The result is shown in the right image. Some artifacts are still noticeable and additional user input might be required

z-axis, perpendicular to the image plane (see Fig. 4). In opposition to traditional compositing, which arranges 2D layers in 3D with a single depth value for each element, deep compositing stores a range of depth values for each object, extending the gamut of editing possibilities. For instance, if the compositing artist aims to integrate an actor with a 3D rendered column of billowing smoke, without 3D deep data in the smoke element, the actor will appear to be in front or behind the column. However, with varying density values in the Z-axis, the actor can be placed *inside* the smoke and show both correct occlusion and partial visibility effects.

In order to mix and compose deep images, a proper depth buffer is required. This data is available for traditional 3D rendered graphics, as each pixel has a depth value associated (Z-buffer), whereas for footage obtained from camera, reliable depth values are available only at some arbitrary specified points. This sparsity is due to the limitations of the capturing device (stereo, time-of-flight cameras, etc.). The remaining pixels are then obtained through interpolation. For instance, Richardt et al. [8] incorporate a time of time-of-flight IR camera to a consumer-level video camera in order to capture a rough depth map which is subsequently filtered to obtain a high-quality depth image by means of spatiotemporal denoising and an upsampling scheme (see Fig. 4).

Although one of the first uses was Pixar RenderMan's deep shadow technique [9], this technology has been progressively adopted by the media industry with the upsurge of 3D cinema and TV. Nowadays, most companies like Weta or DreamWorks rely on deep compositing pipelines

and tools such as Nuke (The Foundry) to create their final compositions.

Visual Transfer and Relighting

The concepts of visual transfer and relighting refer to a set of techniques that aim to transfer some visual properties from the background to the image to be inserted. Illumination (shading, shadows, and highlights) is one of the main visual factors to be considered to homogenize a composition. When real objects have to be introduced into CGI environments with known illumination, this illumination is mimicked with actual light sources in a stage. In the early years of cinema, this technique was necessary when performing background projection (e.g., when recording an actor driving a car by night, the lights from cars or street lamps reproduced in the back screen were synchronized with actual lamps illuminating the actor in the studio). More sophisticated systems like Lightstage [10] have been developed to capture an actor performance.

By combining high-speed cameras and structured light sources from many directions, it is possible to create a database of views of the actor under different light environments which can be interpolated to re-render under arbitrary lighting conditions for compositing in any background (see Fig. 5).

Deep Learning-Based Compositing

In the last decade, the recent advances in deep learning have made possible accurate relighting

Compositing and Chroma Keying, Fig. 4 Example of deep compositing [8]. The fruit basket in the input image (*left*) is extracted from the background (*right* image, colored in *green*) by using the associated depth range data (*middle* image)

Compositing and Chroma Keying,

Fig. 5 Example of image capture in a Lightstage [9]. The actor is illuminated with an even omnidirectional light in order to capture the base reflectance of his face. In further shots at high speed, the light sources are switched on and off individually to capture the interaction with each light source for future interpolation

Compositing and Chroma Keying, Fig. 6 Example of AI-based background removal method. Left: Original image. Right: Novel composition.

and image composition techniques for static images and video alike. The application of generative neural networks to existing media content of actual people has allowed plausible and realistic reenactment (e.g.: lip sync to novel audio), replacement (e.g.: face swapping), editing, and synthesis creating the phenomenon known as *deepfake*, the generation of believable media by a deep neural network.

This has raised increasing awareness and concern over identity control, spurring the research in the field for deep forgery detection. Most detection techniques are based on either artifact-based detectors (abnormal poses and mannerisms, speech and face consistency), or deep learning classifiers (CNN networks), which have shown certain success but also vulnerabilities to adversarial learning attacks. Readers are referred to the survey by Mirsky and Lee [11] for a

comprehensive description of neural architectures and compositing detectors.

Despite these concerning applications, deep learning has also helped by reducing the need for equipment, scene setups, or even chroma-based backgrounds to perform relighting and background compositing. For instance, the creators of Lightstage, leveraged data obtained with controlled illumination to train a self-supervised system to perform relighting of “in the wild” images that were acquired under arbitrary conditions [12].

Moreover, recent deep learning-based matting methods can extract an accurate alpha channel of entire video sequences just by taking an image of the background without the subject, as shown by the generative adversarial network (GAN) proposed by Segunpta et al. [13]. Some commercial applications of AI-based background removal are available online [14], capable of automatically

extract human shapes from an image, even with challenging components, such as hair, as shown in the left silhouette which is extracted and composed with a new background on the right image at Fig. 6.

Definition

Compton scattering is the process whereby a photon (usually a gamma-ray or X-ray) transfers a nonzero fraction of its energy to a charged particle, usually an electron. The particles in the initial and final states are the same (a photon and an electron), making this a scattering process.

For the purposes of this entry, it is assumed that the scatterer is an electron. Typically, this is an atomic electron in a material that has been penetrated by an X-ray or gamma-ray. For lower-energy photons, other processes prevail, such as Rayleigh and Mie scattering or photoelectric absorption.

Photon Interaction Processes

In the visible and UV range, where photon wavelengths are much larger than the atom's size,

interactions tend to be discussed in terms of beams of light impinging on bulk materials using terms such as absorption, transmission, reflection, and refraction. For much higher photon energies in the X-ray and gamma-ray ranges, interactions with individual electrons and nuclei take place. These are typically described in terms of cross sections, although attenuation and absorption coefficients are also widely used for characterizing interaction probabilities in bulk materials. The three main photon interactions for X-ray and gamma-rays are as follows:

- *Photo-electric absorption*, where the photon is completely absorbed and an electron requires enough energy to be ejected by the atom with some kinetic energy
- *Pair-production*, where the photon interacts with the field of the atomic nucleus to produce an electron and a positron (antielectron)
- *Compton (incoherent) scattering*, where the photon scatters off an atomic electron, ejecting it from the atom

This entry covers the third interaction process – Compton scattering.

The Compton scattering process is perhaps most familiar to those working in the field of X-ray and gamma spectrometry, the measurement of gamma and X-ray energies typically in the 1 keV to 3 MeV range, which is the range over which naturally occurring radioactive material (NORM), or natural background radiation, produces photons. Radiation therapists treat cancer patients using electron linear accelerators that produce photon beams in the 6 to 30 MeV range which undergo the Compton process as they deposit their energy in the tumor target. Particle physicists are also very familiar with Compton scattering as it is one of the processes that a high-energy photon, typically many GeV, will undergo as it deposits its energy in a detector's calorimeter through a "shower" process. This starts predominantly as a complex interplay of alternating pair-production and electron/positron *Bremsstrahlung* (radiative photons that in turn undergo pair-production) and eventually gives

way to the Compton and photo-electric absorption processes in the low-energy tail below a few MeV.

History

In the early twentieth century, X-rays were observed to scatter off materials with a wavelength lower than that of the primary beam, in conflict with the classical wave theory (Thomson scattering) assumed at the time which predicted the wavelength would be unchanged. Arthur Haley Compton, an American physicist, provided an explanation for this observation in 1923 [1] by considering the photon as a particle having quantized energy, as with Einstein's explanation of the photo-electric effect, and assuming a billiard ball type of interaction with the electron that satisfied energy and momentum conservation. For this discovery, Compton was awarded the 1927 Nobel Prize in Physics. The Compton effect was also discovered independently by the Dutch-American physical chemist Peter Debye in early 1923, and the Compton-Debye formula is a kinematic description of this effect.

Kinematics

Figure 1 depicts a photon γ with initial energy $E = h\nu$ impinging upon a stationary electron e of rest mass m_e and scattering (γ') at angle θ with

Compton Scattering, Fig. 1 Compton scattering process, $\gamma e \rightarrow \gamma' e'$

energy E' . The electron e' recoils at angle ϕ with energy $E - E'$.

Based on the energy ranges discussed in section “[Photon Interaction Processes](#),” a 1 MeV photon is somewhat representative of the photon energies to be considered. Assuming half this energy (0.5 MeV) is imparted to the electron through the scattering process, the electron would increase in energy by an amount roughly equal to its rest-mass energy of $m_e c^2 = 0.511$ MeV, making the kinematics of the process relativistic. This is easily seen by comparing the initial and final energy of the electron, E_i and E_f , respectively, using Einstein’s equation for a mass at rest and in motion with additional (kinetic) energy $\delta E = m_e c^2$:

$$\begin{aligned} E_i &= m_e c^2 \\ E_f &= m c^2 = \gamma m_e c^2 = E_i + \delta E = 2m_e c^2 \end{aligned}$$

where $\gamma = \sqrt{1 - \beta^2}$, $\beta = v/c$, and v is the final velocity of the electron in the lab frame. Solving yields $\beta \approx 0.87$. Therefore, relativistic kinematics must be used in the calculation of the Compton process.

In the remainder of this entry the natural units of particle physics are used, $c = \hbar = 1$, such that energy [MeV], momentum [MeV/c], and mass [MeV/ c^2] all have the same units [MeV].

The easiest way to proceed is to use four-momentum notation, $P^\mu = (E, P_x, P_y, P_z)$ with $P^2 = P_\mu P^\mu = E^2 - P_x^2 - P_y^2 - P_z^2 = E^2 - \mathbf{P}^2 = M^2$, and write down the energy-momentum conservation equations. Following Fig. 1,

$$q + p = q' + p' \quad (1)$$

where q and p (q' and p') are the initial (final) four-momenta of the photon and electron, respectively. Dropping the subscript on m_e for convenience,

$$q = (E, 0, 0, E) \quad (2)$$

$$p = (m, 0, 0, 0) \quad (3)$$

$$q' = (E', E' \sin \theta, 0, E' \cos \theta) \quad (4)$$

$$p' = (E'_e, -p'_e \sin \phi, 0, p'_e \cos \phi) \quad (5)$$

$$= (E + m - E', -E' \sin \theta, 0, E - E' \cos \theta) \quad (6)$$

where four-momentum conservation has been used in the last line to eliminate the dependence on variables E_e and p_e . Rearranging, squaring, and making use of the invariant mass relations $q^2 = q'^2 = 0$ and $p^2 = p'^2 = m^2$ yields an expression for the scattered photon energy E' as a function of scattering angle:

$$\begin{aligned} (q - q')^2 &= (p - p')^2 \\ -2qq' &= -2pp' + 2m^2 \\ qq' &= pp' - m^2 \end{aligned}$$

This manipulation has the advantage that the x and y components of the four-momentum fall out in both dot products, leaving an expression easily solved for the ratio of scattered to initial photon energy, E'/E :

$$\begin{aligned} EE' - EE' \cos \theta &= m(E + m - E') - m^2 \\ &= m(E - E') \\ EE'(1 - \cos \theta + m/E) &= mE \\ \frac{E'}{E} &= \frac{1}{E/m(1 - \cos \theta) + 1} = \frac{\lambda}{\lambda'} = \frac{k}{k'} \end{aligned} \quad (7)$$

where use has been made of the relation $E = h\nu = hc/\lambda = \hbar ck$ to express the ratio in terms of wavelength (λ, λ') and wave number (k, k'). Figure 2 shows the fraction of initial energy carried by the scattered photon E'/E as a function of scattering angle θ , for different initial energies. For forward-going scatters, the photon retains most of its energy, as these are glancing collisions with small transverse momentum transfer. All photon-scattering angles are kinematically accessible. In the low-energy limit, Eq. 7 reduces to $E' = E$, independent of angle θ , and consistent with expectations from classical wave theory.

By four-momentum conservation, the scattered electron is given additional kinetic energy $T = E - E'$. Its scattering angle ϕ can be

Scattered photon energy versus angle

Compton Scattering, Fig. 2 Scattered photon energy versus angle

constructed by equating the ratio of transverse to longitudinal p' momentum from Eqs. 5 and 6:

$$\begin{aligned} \tan \phi &= \frac{\sin \theta}{E/E' - \cos \theta} \\ &= \frac{1}{(1 + E/m) \tan \theta/2} \end{aligned} \quad (8)$$

where Eq. 7 has been used to substitute for E/E' . Since θ ranges from 0 to π , the maximum scattering angle of the electron is $\pi/2$, as expected from a billiard-ball type of interaction. From inspection of Eq. 7, the minimum energy a scattered photon can have is at $\theta = \pi$ radians,

$$E'_{\min} = \frac{E}{2E/m + 1} \quad (9)$$

i.e., a full back-scatter collision imparting maximum energy to the electron:

$$T_{\max} = E - E'_{\min} = \frac{2E}{2 + m/E} \quad (10)$$

In fact, since $1 - \cos \theta$ is a slowly varying function of θ near π (less than 10% change from 180° to 145°), the electron energy is close to the maximum for a wide range of back-scattered photon angles, leading to the well-known *Compton edge* phenomenon in gamma spectrometry which results from Compton scattering in a gamma detector. This will be made more evident when the cross section is considered in the next section.

Cross Section

Compton also gave an approximate expression for the cross section for photon scattering. The full expression was calculated in 1929 by Klein and Nishina [2], one of the first successful applications of the new Dirac wave theory. The differential cross section (for unpolarized photons) for the production of a scattered photon into solid angle $d\Omega = \sin \theta d\theta d\varphi$ is given by [3]:

$$\begin{aligned} \frac{d\sigma}{d\Omega} &= \frac{\alpha^2}{2m^2} \left(\frac{k'}{k}\right)^2 \left(\frac{k}{k'} + \frac{k'}{k} - \sin^2\theta\right) \\ &= \frac{\alpha^2}{2m^2} \left(\frac{1}{\eta(1 - \cos\theta) + 1}\right)^2 \left(\frac{1}{\eta(1 - \cos\theta) + 1} \right. \\ &\quad \left. + \eta(1 - \cos\theta) + 1 - \sin^2\theta\right) \end{aligned} \quad (11)$$

where $\eta = E/m$, $\alpha = \frac{e^2}{4\pi}$ is the fine structure constant, and Eq. 7 has been used. This reduces to the Thomson cross section [4] at low energy, $\eta \rightarrow 0$ ($k \rightarrow 0$) [3]:

$$\left.\frac{d\sigma}{d\Omega}\right|_{\text{low } E} \rightarrow \frac{\alpha^2}{2m^2} (1 + \cos^2\theta) \quad (12)$$

The cross section is plotted as a function of photon-scattering angle in Fig. 3 for various photon energies.

It is useful to recast the Klein-Nishina cross section in terms of electron kinetic energy, $T = E - E'$, using Eq. 7:

$$\begin{aligned} \frac{d\sigma}{dT} &= \frac{d\sigma}{d\theta} \frac{d\theta}{dT} = 2\pi \sin\theta \frac{d\sigma}{d\Omega} \frac{d\theta}{dT} \\ &= \frac{2\pi}{m} (1 - \cos\theta + 1/\eta)^2 \frac{d\sigma}{d\Omega} \end{aligned} \quad (13)$$

which as a function of T (using Eq. 7) becomes [5]:

$$\frac{d\sigma}{dT} = \frac{\pi r_e^2}{m\eta^2} \left[2 + \frac{s^2}{\eta^2(1-s)^2} + \frac{s}{1-s}(s - 2/\eta) \right] \quad (14)$$

where $s = T/E$. This is plotted for a few photon energies E in Fig. 4. As motivated in section “Kinematics,” these distributions exhibit a characteristic *Compton edge* at the maximum electron energy. This has good and bad consequences for gamma spectrometry (see section “Applications” below).

Integrating over solid angle yields the total Klein-Nishina cross section [5] plotted in Fig. 5 versus photon energy. The cross section approaches the classical wave-theory value at the low-energy limit.

Compton Scattering, Fig. 3 Klein-Nishina cross section for a photon scattering off a stationary electron, versus photon scattering angle θ

Compton Scattering, Fig. 4 Cross section as a function of electron energy T

Compton Scattering, Fig. 5 Klein-Nishina total cross section (solid line) as a function of photon energy. Overlaid as a limit (dashed line) is the low-energy Thomson scattering value calculated from classical wave theory

The Klein-Nishina cross section formula was derived for a free electron at rest. For most applications of relevance, electrons are not free but bound by the nucleus of an atom and have momentum. At very low photon energy $E \rightarrow 0$, the photon has long wavelength and essentially interacts with the atom as a whole (different parts of the atom contributing in a coherent way, hence *coherent scattering*), leaving it in an unexcited state with no energy transfer to it. Individual electrons are not resolved, and the probability for *incoherent* (Compton) scattering goes to zero. As the photon energy increases, energy transfer to individual electrons can take place, starting with those least bound in the outer shells. At still higher energy, all electrons become available to the Compton scattering process, appearing as essentially free electrons at rest (compared to the photon energy), and the Klein-Nishina cross section holds more accurately. The overall result of including binding effects is that the Compton cross section is suppressed at low-photon energy with respect to the Klein-Nishina prediction. This is demonstrated in Fig. 6, which shows the Klein-

Nishina cross section (solid line) overlaid with the Compton cross section for hydrogen (long-dash line) using data from the NIST XCOM database [6]. The two cross sections are in good agreement above about $E = 0.1$ MeV, where the photon has a wavelength of $\lambda = hc/E$ of 0.0012 nm. This is small compared to the size of the H atom (the first Bohr radius has value of 0.0529 nm) so that the electron is resolved, appearing essentially free and at rest. At lower photon energy, the curves diverge rapidly as binding effects come into play.

Applications

There are many applications of Compton scattering in a variety of fields including radiobiology, radiotherapy, nuclear medicine, densitometry, nuclear imaging, gamma spectroscopy, material physics, and astrophysics. Only two are covered here in detail: the energy calibration of organic scintillators used in gamma spectrometry; and gamma imaging for medical or safety and security purposes.

Compton Scattering, Fig. 6 Cross sections as a function of photon energy

Gamma Spectrometry

Scintillators are widely used in gamma spectrometry as materials which convert the kinetic energy of ionizing particles into detectable light in the UV or optical range. The scintillating photons are promptly emitted, typically within a *microsecond* of energy deposition, and their number is to first order proportional to the energy deposited by the charged particle. By capturing and directing these photons efficiently to a photodetector (typically a conventional photomultiplier tube or solid-state silicon-photomultiplier device), the energy deposited can be measured as a current pulse with total charge characterizing the energy deposited. For X-rays or gamma-rays, conversion to charged particles through one or more steps of photoelectric absorption, Compton scattering, or pair-production is required for detection. To calibrate such a system for gamma spectrometry, one relies on one or more radioactive sources (e.g., Cs-137) with emission at known characteristic energies (662 keV for Cs-137). Repeated full-energy absorption of these gamma rays leads to “photo-peaks” in the energy spectrum at the characteristic energies, which can then be used to determine the relationship between charge (or pulse height) and energy.

Of course, gamma rays do not always deposit their energy fully – many might scatter once or more and exit the scintillator. Single-scatter interactions lead to the Compton edge structure exhibited in Fig. 4. Generally, such edges are a nuisance for spectrometry as they can make it difficult to isolate the photopeaks for proper measurement, especially for sources with multiple characteristic energies. However, there is an important class of scintillator which relies heavily on the Compton edge for calibration and measurement. These are organic scintillators having low-atomic number for which the probability of a photo absorption is very low or absent entirely depending upon energy (note the cross-section values at 662 keV in Fig. 6). For example, *poly vinyl toluene* (PVT) is an inexpensive plastic scintillator that is robust, nonhygroscopic, and easily tooled and shaped by the end user in the lab. It is the only economical option for deployment in

bulk at border crossings as giant portal monitors past which shipping containers are driven. Unfortunately, the probability for photo-absorption in PVT is so low in most of the energy range of interest (up to 3 MeV) that one must rely solely on the Compton edge to calibrate these detectors and make use of them for gamma identification [7].

Compton Imaging

A second notable application of Compton scattering is in the imaging of gamma-ray fields. Consider a photon detector capable of measuring the energy and position of interactions taking place in it, and for simplicity assume a point source lies in a nearby field of interest. By measuring the energies of the scattered photon and electron, one can make use of Eq. 7 to deduce the angle θ through which the photon must have scattered. Combined with the positions of the scattering point and the detected scattered photon, this yields a handle on the incoming direction of the photon up to a cone of possible angles. (If the direction of the scattered electron can be measured, then the cone reduces to a sector.) Over time, multiple photon interaction “events” yield enough information to deduce where the source must lie (e.g., through simple overlap of the cones back-projected into the field of interest). Extended sources (nonpoint) are more challenging and require more sophisticated algorithms.

[CIE fundamental color matching functions](#); [Cone spectral sensitivities](#)

Definition

The three cone fundamentals are the spectral sensitivities of the long- (L-), middle- (M-), and short- (S-) wavelength cones measured relative to light entering the cornea. They are also the fundamental color matching functions (CMFs), which in colorimetric notation are referred to as $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$. The simple identity between the cone fundamentals of color matching and the cone spectral sensitivities depends on phototransduction and its property of *univariance*. The absorption of a photon produces a photoreceptor response that is independent of photon wavelength, so that all information about wavelength is lost. With one cone type, vision is monochromatic. With three cone types, vision is trichromatic.

Trichromacy means that for observers with normal color vision, the color of a test light of any chromaticity can be matched by superimposing three independent primary lights (with the proviso that one of the primaries sometimes must be added to the test light to complete the match). The amounts of the three primary lights required to match test lights as a function of test wavelength are the three CMFs for those primary lights (usually defined for matches to test lights of equal energy). Because the cone spectral sensitivities overlap, it is not possible for any real light to stimulate just one of them. However, the cone fundamentals are the three CMFs for the three *imaginary* primary lights that would uniquely stimulate individual cone types (i.e., imaginary

lights that produce the three “fundamental” sensations that underlie color vision). The cone fundamental CMFs define all other CMFs and must be a linear transformation of them.

The cone fundamentals can be determined directly by measuring cone spectral sensitivities using “color-deficient” observers lacking one or two cone types and/or special conditions to isolate single-cone responses. They can also be derived by the linear transformation of CMFs measured using real primary lights, but for that the coefficients of the linear transformation must be known.

Current estimates of the cone fundamentals [1–3] use spectral sensitivity measurements to guide the choice of the coefficients of the linear transformation from a set of measured CMFs to the cone fundamental CMFs.

Overview

The spectral properties of the cone fundamentals and that of color matching, in general, are determined principally by the way in which the cone photoreceptors interact with light at the very first stage of vision. They depend, in particular, on photon absorptions by the cone photopigment and on how the probability of photon absorption varies with wavelength. To understand that, we start at the molecular level.

Phototransduction

The cone photopigment molecule is made up of a transmembrane opsin, a G protein-coupled receptor protein, bound to a chromophore, 11-*cis* retinal. The absorption of a photon provides the energy needed to isomerize the chromophore from its 11-*cis* form to its all-*trans* form; this change in shape activates the opsin and triggers the phototransduction cascade and the neural response. The likelihood that a given photon will produce an isomerization depends upon how closely its energy matches the energy required to initiate the isomerization. Crucially, this energy varies with cone type because of differences in key amino acids in those parts of the opsin molecule that surround the chromophore. These amino acids modify the isomerization energy and thus

the spectral sensitivity of the photoreceptor [4]. In most observers with normal color vision, there are four photoreceptor classes: three types of cone photoreceptors, L-, M-, and S-cones, and a single type of rod photoreceptor.

Cone fundamentals, since they are measured behaviorally in terms of energies measured at the cornea, also depend on the absorption of photons by the optical media and on the density of photopigment in the photoreceptor outer segment, both of which vary between observers (see below). Thus, the cone fundamentals are not *precisely* related to the spectral properties of the photopigments (called the absorbance or extinction spectra).

Univariance

The relatively simple relationship between the cone fundamentals and color matching arises because of the way in which cone (and rod) photoreceptors transduce absorbed photons. When a photon is absorbed to initiate the phototransduction cascade, the effect is all or nothing and is consequently independent of photon wavelength. Photoreceptor outputs thus vary *univariantly* according to the number of photons that they absorb [5], as a result of which wavelength and intensity are confounded, and individual photoreceptors are “color blind.” A change in the rate of photon absorption could be due to a variation in light intensity, but equally, it could be due to a variation in wavelength.

With only one cone type, vision is monochromatic and reduced to a single dimension: two lights of any spectral composition can be made to match simply by equating their intensities (a relationship defined by the cone type’s spectral sensitivity). With only two cone types, vision is dichromatic and reduced to two dimensions: lights of any spectral composition can be matched with a mixture of two other lights. Dichromatic human observers fall into three classes, protanopes, deuteranopes, and tritanopes, depending upon whether they lack L-, M-, or S-cones, respectively. Observers with normal color vision have three classes of cone photoreceptor, and their vision is trichromatic. Color vision depends on

comparing the univariant outputs of different cone types.

Trichromacy

A consequence of trichromacy is that the color of any light can be matched with three specially selected or “independent” primary lights of variable intensity (chosen so that no two will match the third). These primary lights are frequently red (R), green (G), and blue (B), but many other triplets are possible. The upper panel of Fig. 1 shows a typical color matching experiment, in which an observer is presented with a half-field illuminated by a “test” light of variable wavelength λ and a second half-field illuminated by a mixture of red, green, and blue primary lights. At each λ , the observer adjusts the intensities of the three primary lights, so that the test field is

perfectly matched by the mixture of primary lights. The lower left-hand panel of Fig. 1 shows the mean $\bar{r}(\lambda)$, $\bar{g}(\lambda)$ and $\bar{b}(\lambda)$ CMFs obtained by Stiles and Burch [6] for primary lights of 645, 526, and 444 nm. Notice that except at the primary wavelengths one of the CMFs is negative. There is no “negative light”; rather, these negative values indicate that the primary in question must be added to the spectral test light to make a match (as illustrated in the panel for the red primary). Real primaries give rise to negative values because real lights do not uniquely stimulate single-cone photoreceptors (see Figs. 2 and 3). The cone fundamental CMFs are always positive.

CMFs, such as the ones shown in the lower-left panel, can be linearly transformed to any other set of real primary lights and to the *fundamental* primaries that are illustrated in the lower

Cone Fundamentals, Fig. 1 A monochromatic test field of wavelength, λ , can be matched by a mixture of red (645 nm), green (526 nm), and blue (444 nm) primary lights, one of which must be added to the test field to complete the match (*upper panel*). The amounts of each of the three primaries required to match monochromatic lights spanning the visible spectrum are the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs (*red, green, and blue lines, respectively*) shown in the lower left-hand panel. These CMFs were measured

using 10-deg diameter targets by Stiles and Burch [6]. A negative sign means that the primary must be added to the target to complete the match. CMFs can be linearly transformed from one set of primaries to another and to the fundamental primaries. Shown in the lower right-hand panel are the 10-deg $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs linearly transformed to give the $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ 10-deg cone fundamental primary CMFs (*red, green, and blue lines, respectively*)

Cone Fundamentals,

Fig. 2 Mean cone spectral sensitivity data [10, 11].

L-cone data from deuteranopes with either the L(S180) (red squares, $n = 17$) or L(A180) (yellow circles, $n = 3$) polymorphism, M-cone data from protanopes (green diamonds, $n = 9$), and S-cone data (blue triangles) from S-cone monochromats ($n = 3$) and below 540 nm (measured under intense long-wavelength adaptation) from normal observers ($n = 5$)

right-hand panel of Fig. 1. The three fundamental primaries (or “Grundempfindungen” – fundamental sensations) are the three imaginary primary lights that would *uniquely* stimulate each of the three cones to yield the L-, M-, and S-cone spectral sensitivity functions (such lights are not physically realizable because of the overlapping spectral sensitivities of the cone photopigments). All other sets of CMFs depend on the fundamental CMFs and should be a linear transformation of them. Note that the fundamental CMFs shown here are comparable to those shown in Fig. 3 but are plotted as linear sensitivities rather than as the more usual logarithmic sensitivities.

The relationship between the fundamental CMFs and a set of real CMFs (obtained using, e.g., red, green, and blue primaries) can be stated formally: When an observer matches the test and mixture fields in a color matching experiment, the two fields cause identical absorptions in each of his or her three cone types. The match, in other words, is a match at the cones. The matched test and mixture fields appear identical to S-cones, to M-cones, and to L-cones. For matched fields, the following relationships apply:

$$\bar{l}_R \bar{r}(\lambda) + \bar{l}_G \bar{g}(\lambda) + \bar{l}_B \bar{b}(\lambda) = \bar{l}(\lambda)$$

$$\bar{m}_R \bar{r}(\lambda) + \bar{m}_G \bar{g}(\lambda) + \bar{m}_B \bar{b}(\lambda) = \bar{m}(\lambda) \quad (1)$$

$$\bar{s}_R \bar{r}(\lambda) + \bar{s}_G \bar{g}(\lambda) + \bar{s}_B \bar{b}(\lambda) = \bar{s}(\lambda)$$

where $\bar{l}_R$, $\bar{l}_G$, and $\bar{l}_B$ are, respectively; the L-cone sensitivities to the R, G, and B primary lights; and similarly, $\bar{m}_R$, $\bar{m}_G$, and $\bar{m}_B$ and $\bar{s}_R$, $\bar{s}_G$, and $\bar{s}_B$ are the analogous M- and S-cone sensitivities. Since the S-cones are insensitive in the long-wavelength (red) part of the spectrum, $\bar{s}_R$ can be assumed to be zero. There are therefore eight unknowns required for the linear transformation:

$$\begin{pmatrix} \bar{l}_R & \bar{l}_G & \bar{l}_B \\ \bar{m}_R & \bar{m}_G & \bar{m}_B \\ 0 & \bar{s}_G & \bar{s}_B \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} \bar{l}(\lambda) \\ \bar{m}(\lambda) \\ \bar{s}(\lambda) \end{pmatrix}. \quad (2)$$

Since only relative cone spectral sensitivities are required, the eight unknowns reduce to five:

$$\begin{pmatrix} \bar{l}_R/\bar{l}_B & \bar{l}_G/\bar{l}_B & 1 \\ \bar{m}_R/\bar{m}_B & \bar{m}_G/\bar{m}_B & 1 \\ 0 & \bar{s}_G/\bar{s}_B & 1 \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} \bar{l}(\lambda) \\ \bar{m}(\lambda) \\ \bar{s}(\lambda) \end{pmatrix} \quad (3)$$

A definition of the cone fundamental CMFs in

Cone Fundamentals, Fig. 3 Comparisons between estimates of the 2-deg L-, M-, and S-cone fundamentals by Stockman and Sharpe [2] (solid-colored lines), by Smith and Pokorny [1] (dashed lines), and by König and Dieterici [17] (symbols)

terms of real CMFs requires a knowledge of the coefficients of the transformation.

Spectral Sensitivity Measurements

The transformation in Eq. 3 can be estimated by comparing dichromatic and normal color matches [7]. Dichromats confuse pairs of colors that trichromats do not. When these confusions are plotted in a normal chromaticity diagram, they yield characteristic lines of confusion that converge to a different confusion point for each type of dichromat. The three confusion points correspond to the chromaticities of the missing imaginary

fundamental primaries, from which the transformation matrix can be derived.

An alternative, straightforward way of estimating the transformation matrix is to measure the three cone spectral sensitivities directly. This can be achieved using steady or transient chromatic backgrounds to selectively adapt one or two of the cone types to isolate the third [8, 9]. However, cone isolation can more easily be achieved by using chromatic adaptation in observers in dichromats lacking one (or two) of the three cone types. With the S-cones selectively adapted, L- and M-cone spectral sensitivities can be directly measured in deuteranopes without M-cone function and in protanopes without L-cone function. Figure 2 shows the mean spectral sensitivity data obtained from nine protanopes (green diamonds), from seventeen single-gene L(S180) deuteranopes with serine at position 180 of their L-cone photopigment opsin gene (red squares), and from five single-gene L(A180) deuteranopes with alanine at position 180 (orange circles) [2, 10]. L(A180) and L(S180) are two commonly occurring L-cone photopigment polymorphisms in the normal human population that differ in $\lambda_{\max}$ by about 2.5 nm [10]. Figure 2 also shows the mean S-cone spectral sensitivities obtained from three S-cone monochromats, who lack L- and M-cones, and under intense long-wavelength adaptation at wavelengths shorter than 540 nm obtained from five normal subjects [11]. Importantly, thanks to molecular genetics, we can now choose dichromats or monochromats for these experiments whose remaining cone photopigments are normal.

Cone Fundamentals

The spectral sensitivities shown in Fig. 2 were used by Stockman and Sharpe [2] to find the linear combinations of the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs that best fit each measured cone spectral sensitivity, allowing adjustments in the densities of pre-receptor filtering and photopigment optical density in order to account for differences in the mean densities between different populations

and different target sizes. The transformation matrix for the Stockman and Sharpe 10-deg cone fundamentals is

$$\begin{pmatrix} 2.846201 & 11.092490 & 1 \\ 0.168926 & 8.265895 & 1 \\ 0 & 0.010600 & 1 \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} \quad (4)$$

where $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs are the Stiles and Burch CMFs measured with a 10-deg diameter test field [6]. The Stockman and Sharpe 2-deg estimates are based on the same transformation but the cone fundamentals have been adjusted to macular and photopigment optical densities appropriate for a 2-deg target field. The 2-deg functions are shown in Fig. 3 as the solid-colored lines. The Stockman and Sharpe 2-deg and 10-deg functions have been adopted by the Commission Internationale de l'Éclairage (CIE) as the 2006 physiologically relevant cone fundamental CMFs [3].

The quality of cone fundamentals depends not only on the correct transformation matrix but also in the CMFs from which they are transformed. The Stiles and Burch 10-deg CMFs [6], which were measured in 49 subjects from approximately 390–730 nm (and in nine subjects from 730 to 830 nm), are probably the most secure and accurate set of existing color matching data. Other CMFs are less secure and typically flawed [12].

Most other cone fundamentals are also given in the form of Eq. 4 but for different underlying CMFs [1, 2, 13–16]. The most widely used have been those by Smith and Pokorny [1]. Their transformation matrix is

$$\begin{pmatrix} 0.15514 & 0.54312 & -0.03286 \\ -0.15514 & 0.45684 & 0.03286 \\ 0 & 0.00801 & 1 \end{pmatrix} \begin{pmatrix} \bar{x}(\lambda) \\ \bar{y}(\lambda) \\ \bar{z}(\lambda) \end{pmatrix} \quad (5)$$

where $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are the Judd-Vos-modified 2-deg CMFs [15].

Figure 3 shows the Smith and Pokorny estimates as dashed lines and for historical context the much earlier estimates obtained 125 years ago by

König and Dieterici [17] as symbols. For the L- and M-cone fundamentals, the discrepancies between the more modern fundamentals are mainly at shorter wavelengths; the discrepancies between the S-cone fundamentals are more extensive.

The functions mentioned here can be found at <http://www.cvrl.org>

Other Factors that Influence Cone Fundamentals

Factors other than the properties of the photopigment also affect the cone spectral sensitivities. They include the density of the pigment in the lens that absorbs light mainly of short wavelengths, the density of macular pigment at the fovea, and the axial optical density of the photopigment in the photoreceptor. All three factors exhibit individual differences between observers, and the last two vary with retinal eccentricity. These factors should all be taken into account when trying to predict the spectral sensitivities of an individual from standard functions such as those defined by Eqs. 4 and 5 for a given target size and eccentricity. See, for example, Brainard and Stockman [18] for further details.

Crawford, Brian Hewson

Robert W. G. Hunt

Department of Colour Science, University of Leeds, Leeds, UK

1906–1991

Biography

Brian Hewson Crawford was a British physicist who made important contributions to the science of vision, colorimetry, lighting, and color rendering.

Brian Crawford was born in 1906 and died in 1991. His first scientific publication was, as his mother's ghostwriter, the Boy's Own Corner of the Daily Mail. He went to the University College London, graduating with first-class honors in Physics at the age of 19. After a brief spell at the Rodenside Laboratory of the photographic company, Ilford, he joined the staff of the National Physical Laboratory (NPL) in 1927.

Having very wide interests, Crawford explored languages, painting, and music. His attitude to life was well illustrated by his remark after breaking his wrist in a fall from a bicycle that it had a reset at a more convenient angle for playing the viola.

His honors included his Doctorate of Science from the University of London and his Newton Medal from the Colour Group (Great Britain).

Major Accomplishments/Contributions

Crawford worked in the NPL with W. S. Stiles under the leadership of John Walsh. A brilliant series of papers followed in the Proceedings of the Royal Society, on such new topics as equivalent backgrounds, increment thresholds, and, above all, the directional sensitivity of the retina to light and color known as the Stiles-Crawford effects. These were discovered during attempts to build a visual photometer based on pupillometry. The then “usual assumption that the apparent brightness of an object is proportional to the pupil area” was soon demolished [1–3].

Good fortune in research was characteristic of both Crawford and Stiles, but important discoveries fall only to those who deserve them. Crawford would say that you only had to search about in any field and you were bound to find out something interesting. No doubt this was so in his case. His 1947 *Proc. Roy. Soc.* paper on “Visual Adaptation in Relation to Brief Conditioning Stimuli” [4] is not obviously inspired by temporary blinding effects of gunfire flashes during the Second World War, but that was how “Crawford masking” was discovered. This is the effect whereby “a luminal stimulus begins to rise before the conditioning stimulus is applied to the eye.”

To compare and contrast the large-field colorimeters which Stiles and Crawford had each constructed in adjacent laboratories is an interesting exercise. Stiles’ machine was workshop built to the highest NPL precision and endowed with such facilities as a meteorology station of hygrometers, barometers, and thermometers, to monitor changes in the refractive index of the air. Crawford’s apparatus belonged to the string and sealing wax tradition, with corks for nonslip knobs and strips of graph paper for scales. Both instruments served their respective purposes admirably.

The successful early partnership and later divergence of Crawford and Stiles are perhaps explained by the creative tension between

opposite natures. To draw an analogy from art, Stiles’ science was classic; like Nicolas Poussin, he had neglected nothing. Crawford was a romantic; he was fond of quoting Maxwell’s dictum that it is always worth playing a trombone to a petunia at least once, and you never know what might happen. But Crawford could work to the highest NPL precision and accuracy when required, as he did in determining the average scotopic spectral response of the human eye, which forms the basis of the present CIE definition [5]. Not least was the difficulty of eliminating the effects of minute amounts of stray light and simultaneously discrediting data produced by several investigators who had not been so careful.

In his last years at NPL, Crawford studied the color rendering properties of artificial light sources, and he made a great breakthrough in convincing suspicious experts in art galleries and hospitals that certain fluorescent lamps were suitable for their exacting requirements [6]. Typical of Crawford was his finding that combinations of tungsten filament lamps and “radar blue” fluorescent lamps could imitate almost perfectly any phase of natural daylight. The resultant equipment was essential in providing a transportable reference illuminant for the darker corners of the Victoria and Albert Museum and the Sheffield Royal Infirmary. He also studied color matching and adaptation [7].

Work in the conservation department of the National Gallery was continued by Crawford long after officially retiring from NPL. He also made investigations on color in the laboratories of the University of Edinburgh, the Paint Research Association, Imperial College, and the Institute of Ophthalmology. He went on publishing original papers until the age of 79, thus refuting the fallacy that scientific research is only for young people [8].

Cross-cultural Communication

Jules Davidoff
 Department of Psychology, Goldsmiths
 University of London, London, UK

Definition

Cultural variation and the role of the color lexicon in color tasks

Introduction

The pioneering studies of cross-cultural communication of color were those of Brown and Lenneberg [4], and its follow-up by Lantz and Steffle [11]. Their work came from the Whorfian perspective that language influences thought and was pursued, in the particular, by studying how color information can be communicated to another person. In their seminal investigation, Brown and Lenneberg [4] reported a positive correlation between a range of measures of codability for colors (speed of naming, consensus, communication accuracy) and the accuracy with which those colors were recognized. In particular, the focal or best example of a color is better remembered. However, Agrillo and Roberson [1] showed that the advantages found for coding and recognition of (focal) best examples of English

color categories result from the tight (Whorfian) links between linguistic and cognitive organization of categories, not from any inherent natural goodness of focal colors over other colors. When task demands are well-controlled, so that recognition need not be dependent on name retention, focal colors are no easier communicated than other colors. They argued that color terms define cognitive organization of colors; an idea that has proved useful even to the understanding the mechanisms whereby a population of autonomous agents (robots) could arrive at a repertoire of perceptually grounded categories that is sufficiently shared to allow successful communication [15].

Not all agree on the importance of color lexicons for communication about color. Lindsey, Brown, Brainard, and Apicella [12] observed a low consensus in color naming across Hadza observers, a remote hunter-gatherer society in Tanzania. They took this as evidence for a low evolutionary level of the Hadzane color lexicon. Most importantly, their study discovered a latent pattern of color naming across the speakers of the Hadzane language that did in fact reflect the English color lexicon, which is supposed to be a high evolutionary stage of color naming. Witzel [16] has suggested that the interpretation of the Hadzane data is complicated (confounded) by the variation in saturation of their color samples, but despite its importance, it is not pursued here. This chapter will not be much concerned with the origins of color categories but will consider the importance of color lexicons or more simply color names in color communication. It will show a complex picture. Gibson et al. [8] found that, when comparing the language of remote hunter-gatherers to Spanish, the variability of naming in the indigenous language leads to poorer communication for them about a colored stimulus though all languages communicated better about “warm” rather than “cool” colors. However, names were clearly of importance. Therefore, it is important to consider the precise task for which different cultures produce behavior that is or is not influenced by color lexicons. To start, the first question to consider is about behavior in

languages where colors are deemed to be similar enough to be given the same name.

Kay and Kempton (1984): Two Ways of Seeing Color Similarity

Brown and Lenneberg [4] found that the lack of terms in the Zuni language to distinguish between orange and yellow did not affect the ability to distinguish between colors in those regions. More recently, it has been shown (see [5]) that color categories do not derive from observers becoming more sensitive to colors at the boundary between two color terms. Thresholds and boundaries were comparatively assessed in English and Korean speakers. These languages differ in their color terms, but speakers all had the same threshold sensitivity irrespective of whether the color examined was at a boundary in one of the languages. These results bring us to the classic cross-cultural study of the different approaches to color similarity [9].

In Kay and Kempton, observers were presented with a triad of colors going from blue (A) to green (C) with an in-between color (B) that was half-way between the two in color space. However, (B) was chosen so that its color name was either that of (A) or (C) for English speakers. The importance of the study comes from the demonstration that observers showed two ways of making color judgments. If instructions were set to emphasize comparisons between two stimuli from the same color category, the observers did not find that (B) was more like (A) or (C). If the instructions were set so that the observer had to look at all three colors, then the odd-one-out chosen was the one from a different category – a result mostly replicated in other cross-lingual comparisons (see [5]). The observers were not told to name the colors to decide on their answers, though of course they could have. Kay and Kempton [9] report that observers did not name the colors, rather their choices were made, as one observer put it, according to the one “that looked different.” If so, the communication about the odd-one-out occurs because of a phenomenon known as categorical perception where color space has become

altered by the formation of a category, and so the color in the different category stands out. Most studies using the odd-one-out paradigm use only three colors, and so the categorical advantage could be explained from the observers naming the colors. More recently, studies have embedded the different color in many other identical colors, and hence the task becomes one of visual search. If latencies to perform such a task show a categorical advantage as well as short latencies, categorical perception can be inferred. No such studies have yet been published from remote cultures (see [5]).

The Kay and Kempton study also employed observers from a Mexican culture (Tarahumara) that has a *grue* language (same word for what in English is called green or blue) as well as English-speaking observers from the USA. It was only for the English speakers that there were two ways of responding. The critical proposal in Kay and Kempton [9] is that there are two ways of carrying out color decisions. Their argument is that both ways are perceptual, but one is based on categories and hence has potential for supporting the Whorfian position.

Recent physiological and neuroimaging research finds support for these two ways of making color similarity decisions [3]. Physiological evidence from the macaque for a red/green decision had suggested that the two ways are in competition with reciprocal activity of a population of cells encoding categorization and another population for discrimination. When the task changed, then the network of neuronal activity changed. A similar dual action has been found in human neuroimaging in a comparison between color naming and a task where attention was directed away from the same colors [3]. It was only when the task was color naming that a cortical area (in the temporal cortex around the human V4) was found that represented colors with greater within-category similarity. Subsequent studies (see [5]) employed a distracter task for which hue differences were irrelevant. Now, the brain area for which category difference was important, but hue distance unimportant, was found to be in the dorsolateral prefrontal cortices, whereas the visual cortex was the area interested in the metric

distance between colors. There was no category effect at any language related area, but one does have to ask how a frontal network for color categories was formed without language.

These recent findings relating brain area to the two ways of assessing color similarity raise important questions of the tasks used to investigate color similarity and the conditions that promote the use of a categorical code. The first of these tasks to be considered is simple and has a considerable history. It is the apparently uncontentious task of sorting colors.

Free-Sorting

Similarity and hence the number of categories could be determined by the closeness, in color space, of the to be sorted colors – this would be the physiological similarity way in Kay and Kempton. The physiological way could also be the categorical way if categories are determined by our physiology [10]. Boster [2] argued for this possibility in a task where English speakers were asked to sort eight colors (one example of black, white, red, yellow, green, blue, orange, and purple) in two groups and then to make further divisions to form three groups, four groups, and so on until there were eight groups each of one color. The performance of English speakers was found to mimic the evolutionary theory of Berlin and Kay. Boster's study has not been repeated for observers with smaller numbers of color terms.

Color sorting could, of course, also be carried out by Kay and Kempton's categorical way of seeing. Here one would normally assume that the color terms were learned and not innately (physiologically) driven. However, there are yet other explanations of color sorting that have come from cross-cultural studies. What to us are peculiarities in the free-sorting of color patches were noted by Luria [13] in his investigations of the Uzbeks, Luria was surprised at the allocation of their colors. Sorting did not depend upon what an English speaker would consider obvious. When asked why they had not put two orange-brown colors together, they said "It can't be done" "this is like calf's dung and this is like a peach; you

can't put them together." Here colors are considered not to be independent of objects an idea which has returned to those concerned with the origin of color categories [5]. What should also be noted is the wide variation in the number of color categories produced in the free-sorting task (see [5]). For example, a study of free-sorting 20 colors by speakers of Quechua (a five color-term language of Honduras) noted that they formed more groups than the terms in their language. However, studies of South African languages were less clear. A much more comprehensive study across a large number of languages was therefore undertaken by Roberson, Davies, Corbett, and Vandervyver [14]. Some important and perhaps surprising conclusions can be drawn from their data. They asked their observers to sort 65 stimuli drawn at roughly equal distances in color space between neighboring pairs of colors. If there is some underlying tendency in all observers to group certain colored stimuli together, then all observers should produce the same number of groups (categories) irrespective of the number of color terms in their language. What is immediately clear (see Table 1) is that this is not the case. Languages with around 11 of Berlin and Kay's basic terms (see [9]) do indeed produce a very similar number of groups; a result that might reflect the importance of those categories but could also be due to the similar color-cultural environments of first-world societies. However, the more interesting data in Roberson et al. [14] concern speakers of languages with few color terms; they produced much larger numbers of groups. Take, for example, the Himba – a people from remote Namibia – who have only 5 color terms but sorted the 65 stimuli into, on average, 21 groups. Do the Himba really have 21 color categories or are their responses being determined by other aspects of the task? Roberson et al. [14] noted many observers who formed groups based on brightness or saturation instead of hue; furthermore, sorting might be based on non-color factors. In the case of the Himba, recent research suggests that they are biased to concentrate on local aspects of a display [6]; this may explain a desire to accentuate dissimilarities between the colors and make a large number of small groups. Whatever

Cross-cultural Communication, Table 1 Basic colour terms are not important for communication from sorting. Roberson et al. [14]

Language	Sample size	Number of groups	Confidence limits $\pm 1.96SE$	Number of basic terms
Russian	75	13.5	1.72	12
Turkish	23	13.2	2.78	12
English 1	18	13.7	3.66	11
English 2	47	12.4	1.92	11
Tsakhur	19	11.3	2.16	11
Damara	40	10.5	0.43	11

Tswana	44	17.3	1.92	6
Shona	17	12.4	1.61	6
Berinmo	17	20.3	0.69	5
Himba	21	21.4	4.10	5

the cause of their categorization performance, it is clear that neither the proposed universal color categories nor indeed their own color categories are a dominant force in their sorting behavior. Indeed, the same conclusion comes from the futile attempts of aphasic patients with normal color vision to sort colors (see [5]).

Matching-to-Sample

Another task where color categories (names) could inform a categorization task, but do not, is matching-to-sample. In a study comparing Himba with British observers [7], typical examples of two categories (e.g., green and blue) were presented, and the observer was asked which of these two was more similar to an intermediary color sample. The point of the study was to see if the sample was always matched to the color from the same category. Both for the Himba and the British sample, this was not the case. For example, British observers were shown typical examples of blue and green and asked to match a range of colors that were less typical examples of blue and green to one of the typical colors. The

range of intermediary colors was either centered at the blue/green boundary or shifted so that the middle of the range was clearly more like one of the two typical examples. A comparable task was given to the Himba using two of their color categories. Neither British nor Himba observers made use of color names/categories to make their decisions; both cultures matched equal number of samples to the two typical colors. Here a strategy of equal allocation overrode any decision based on color categories. Thus, Davidoff et al. [7] makes it clear that cultures may choose to ignore color categories even when they could be thought to be useful. It may even be the case that some cultures do not have the concept of color (see [5]). A famous comment of a Polynesian observer that “we don’t talk much about color here” makes the point that distinguishing between hues is not of interest to every culture.

Concluding Remarks

It is surprising that categories are not more important for communication in free-sorting and matching-to-sample if we consider our impression

of the color chart used by anthropologists/psychologists to study color terms. The immediate impression is not of colored stimuli seamlessly merging into those around them but of divisions within the display that conform to our color names. In the widely used display (see [5]), if asked exactly where the divisions occur, some deliberation might be required, but there is no doubt that the appearance is of a categorically organized display. So, it is reasonable to assume that color categories (and possibly their names) are of some importance to our processing and communication of colors. However, it is clear from Roberson et al. [14] and Davidoff et al. [7] that observers from many languages do not spontaneously name colors and/or use those names to communicate in color tasks. Of course, that only prompts the question of why some tasks/cultures are more inclined to use color names.

Definition

Crowdsourcing of multilingual color names refers to distributed experimental methodologies designed to collect large datasets of color naming responses in different languages from a large number of observers over the Internet.

Color Naming

Color naming links vision and language. It describes the intriguing cognitive capacity of humans to communicate about regions of color space using category labels, for example, yellow, navy blue, and dark olive green [1]. A small number of basic color terms, corresponding to the English white, black, red, yellow, green,

blue, brown, orange, pink, purple, and grey, are shared and comprehended well by most speakers in many languages [2]. Yet, color names vary across languages, lexically, in number and in range of reference. To augment color communication within and between different languages, it is necessary to have a worldwide method for gathering the words and phrases that people use to describe a wide range of colors [3, 4].

Color systems are usually three-dimensional geometric spaces that allow the description of colors with numerical coordinates. The representation of perceived colors in such spaces can be very useful for specifying the referents of color names in terms of their coordinates. Using color systems in cross-cultural research enables measurements of differences and similarities of color categories across languages. In Fig. 1 are shown subdivisions of a continuous color plane into English and German lexical color categories, based on the responses of human observers in a color naming experiment [5]. It is interesting that not only the names are different (language-dependent) but also the boundaries of the corresponding regions. For example, the region for *hellblau* in German is larger than the region for *light blue* in English.

Crowdsourcing and Laboratory Color Naming Studies

Human-centered color naming studies are traditionally performed in controlled laboratory settings and involve predefined naming lists (e.g., restricting the responses to a limited number of single word terms) and labor-intensive tasks for a small number of observers [6–8]. Despite the usefulness of calibrated experiments in the field of color science, experimenters face several limitations. First, the controlled viewing conditions, while advantageous for accurate colorimetric specification of stimuli, limit the validity of the predicted color naming functions in real-world settings. Second, the pool of available observers is often constrained to a small number of college

Crowdsourcing of Multilingual Color Names, Fig. 1 Classification synthetic image (left) by observer-based color names in English (middle) and German (right). Each category is represented by the color of its centroid [5]

students or to the authors of the study, which makes it difficult to generalize the results to heterogeneous groups of the population. Third, the large individual differences reported in color naming studies makes the generalization of laboratory experimental findings open to doubt. Also, constrained color naming methods are able to capture only a small fraction of the richness of color languages of the world and the labeling of large regions of color space remains ambiguous. For example, Fig. 2 shows the percentage of number of words used by subjects in an unconstrained color naming experiment [4]. Constraining the responses only to the 11 basic color terms would account for 29% of the responses while to single words would account only for 52% of the responses for naming stimuli across the full color gamut.

On the other hand, web-based color naming experiments provide greater ecological validity than traditional approaches by allowing simultaneous participation of observers in their own familiar spaces, in their own time, with their own equipment and without the physical attendance of the examiner [4, 9]. They also avoid the restrictions of the usual methods which have a small number of observers and/or a limited set of monolexic color terms. Instead, thousands of observers from linguistically and demographically diverse populations are able to name freely a large number of colors online and produce larger color lexicons that improve the precision of color names. Online methods also depart from previous

Crowdsourcing of Multilingual Color Names, Fig. 2 Number of words used by subjects in an unconstrained color naming experiment in English. In red proportion of 11 basic color terms, in blue single words non-basic terms, in green two-word color names and in orange color names consisting of three-words or more [4]

research by distributing the color naming task over a large population. In the collection of multilingual color naming data, online experiments extend earlier cross-cultural studies, which typically used only the most saturated color samples on the surface of the Munsell system, by also sampling the interior of the color solid [2, 3]. Yet, online experimental methodologies often receive criticism as not meeting the exacting standards demanded for rigorous color research

Crowdsourcing of Multilingual Color Names, Fig. 3 Overall flowchart of web-based color naming experiment [9]

because of the uncalibrated color reproduction and viewing conditions. For example, different participants may use different display technologies and browsers and they may view the color stimuli from different distances and viewing angles under various illumination conditions [9]. Furthermore, the motivation of participants varies in both reward-based and in volunteering-based crowdsourcing, and screening the quality of the responses is a major challenge. However, the practical success of sRGB in color encoding for Internet applications has greatly improved the consistency of displayed colors and people exhibit a remarkable ability to describe consistently the color of objects in a continually changing visual world. The robustness of crowdsourcing experimental results can be assessed by whether or not their variability is larger than the variability in laboratory-based studies [4, 7, 9].

Crowdsourcing Color Naming Experiments

To understand the workings of crowdsourcing, a number of online color naming experiments are

briefly reviewed. Nathan Moroney [9] was the first to publish the results of an unconstrained web-based color naming experiment. More than 700 participants were asked to give the best names for seven patches of color selected randomly from a $6 \times 6 \times 6$ uniform grid sampling of the RGB cube, viewed on their own displays against a white background. Figure 3 shows a simplified flowchart of this experiment to create a dynamic website that presents colors and collects color naming responses.

Findings of the online experiment of Moroney [9] were validated against the results of Boynton and Olson [6] and Sturges and Whitfield [8], both obtained under controlled laboratory conditions. The comparisons showed a high degree of correlation for the chromatic basic color terms in terms of hue angles in CIELAB with a linear fit of $R^2 = 0.99$ and $R^2 = 0.98$, respectively. The same comparison but for 27 common color names against the results of a subsequent web-based study resulted in a linear fit of $R^2 = 0.99$ [4]. In 2008, DoloresLabs publicized the results of an online color naming survey conducted via Mechanical Turk to collect a small number of responses for a large number of colors. In the

raw dataset, a total of 1966 distinct color descriptions were collected for 10,000 randomly sampled colors in the RGB cube. An analysis of the DoloresLabs dataset by [10] showed a good correspondence for colors on the surface of the Munsell system with the results of the World Color Survey (WCS) for red, brown, and purple but hue shifts for blue and green [3]. The analysis of data across the full color gamut revealed two additional consistent categories at the lavender and cyan regions that do not correspond to any salient region in the WCS data (Fig. 4).

In 2010, the author of the web comic XKCD, Randall Munroe collected a dataset of 3.4 million unconstrained responses mainly in English. This very large dataset is associated with metadata regarding the gender, language skills, color-blindness of the subjects, and information about their monitor settings. Observers were free to name as many sets of color swatches as they liked, presented against a white background. Each color swatch was uniformly sampled from the full RGB cube. An analysis of the publicly available dataset by Heer and Stone [11] showed clusters that correspond well to the basic color terms identified by Berlin and Kay [2].

In 2009, Mylonas and MacDonald launched an ongoing color naming experiment to collect broad sets of color names within different languages with their corresponding color ranges in sRGB and Munsell specifications over the Internet [4]. Each observer was presented with a sequence of 20 color patches randomly selected from 600 simulated Munsell samples, presented against a neutral grey background. The color naming responses were associated with metadata regarding the response time, color deficiency, hardware/software components, viewing conditions, gender, and cultural background of the observers. An analysis of the data for the most important color names suggested the extension of the English inventory from the 11 basic color terms of Berlin and Kay [2] to 13 basic terms including a lilac and a turquoise category ([12]; see also [10]). Except blue, comparisons of

centroid location of the basic color terms in different languages showed a good correspondence ($>5\Delta E_{00}$) despite the online experimental methodology and the linguistic diversity of the observers [5, 13]. However, the agreement between British and American English ($\Delta E_{00} = 1$) was better than the agreement between English and non-English color languages [14]. Figure 5 shows the location of the thirty most frequent color names offered by a large number of British and American English speakers in the online color naming experiment. The online experiment was also validated directly against an unconstrained color naming experiment using the same stimuli on a calibrated CRT monitor in controlled viewing conditions [7]. The agreement ($<5\Delta E_{00}$) for the location of the basic color terms between the web- and laboratory-based experiments was satisfactory and superior to the agreement ($>7\Delta E_{00}$) between previous laboratory-based studies [6, 8].

Conclusions

Crowdsourcing experimental methodologies offer considerable advantages over traditional approaches for obtaining richer color naming datasets in multiple languages. Comparisons between the results of web- and laboratory-based studies show that the locations of color categories correspond well and support the validity of both methods in estimating color naming functions in calibrated and uncalibrated monitor settings. Moreover, the overall good agreement between the location of corresponding basic color terms in multiple languages confirms that speakers of different languages tend to categorize colors into basic color terms similarly but differences do exist, especially in the blue region and between nonbasic categories. New mobile display technologies and online platforms offer new capabilities and present new challenges to researchers for conducting color naming research over the Internet.

Leeds, Leeds, UK

Biography and Major Accomplishments/Contributions

John Dalton was an English chemist, physicist, and meteorologist who is best known for his work in the development of modern atomic theory and his research into color blindness.

Dalton was born in the county of Cumberland in England in 1766 and received his early education from his father who ran a private Quaker school. He started his own school aged 11, and at age 15 he joined his brother teaching in a school in Kendal [1]. He was barred from attending English universities

because he was a dissenter (a Christian opposed to state religion and mandatory membership in the Church of England) but acquired scientific knowledge from John Gough, a blind philosopher with wide-ranging scientific interests. However, in 1793, he was appointed as teacher of mathematics at New College, Manchester (a dissenters' college). On 3 October 1794, Dalton was elected as a member of the Manchester Literary and Philosophical Society, and a month later he presented his first paper entitled, *Extraordinary Facts Relating to the Vision of Colors with Observations*. The society's *Memoirs and Proceedings* has been published continuously since its first edition which, when it was launched in 1783, was the only regular scientific journal in the United Kingdom except for the *Philosophical Transactions of the Royal Society*. As a result of this paper, congenital color vision deficiency is still referred to as "Daltonism" because he was the first to describe the condition in detail, and the paper also stimulated great debate among other investigators [1]. In 1800 he left New College and began private teaching, and in 1808 he published the atomic theory for which he is most famous. He became President of the Manchester Literary and Philosophical Society in 1817, a post he retained until his death in 1844.

Dalton's Color Blindness

Dalton noticed that only males were afflicted with his condition, and we now know that color

blindness, or color deficiency as it may more properly be referred to, is much more prevalent among males than females. He also recognized that the condition must be hereditary since he and his brother had the same condition.

In his 1794 letter, Dalton wrote:

The flower was pink but it appeared to me almost an exact sky-blue by day; in candlelight however it was astonishingly changed, not having then any blue in it but being what I call red – a colour which forms a striking contrast to blue.

Thirty-six years prior to Dalton's famous 1794 letter, Thomas Young had postulated that congenital color vision defects arose from the photoreceptors, but Dalton refused to believe it [1]. As a result of his meticulous observations, Dalton believed that the fluids in his eyes must contain a blue colorant, and he instructed that on his death his eyes be subject to a postmortem analysis. No trace of the blue colorant was found. Interestingly Dalton found 25 others (including, notably, his own brother) who suffered the same failure of color constancy. Dalton also wrote that the red end of the spectrum was "little more than a shade or defect of light."

We now know that Young was essentially correct, that is, that congenital color vision defects result from genetic mutations that mean that one (or more) of the three visual pigments found in the cones of our retina has anomalous spectral absorption properties or is absent entirely. Young believed that Dalton was a protanope – that is, that he was missing the long-wavelength sensitive visual pigment. Although the postmortem examination of Dalton's eye did not reveal the blue colorant that Dalton had predicted, the remaining eye was preserved between two sheets of glass until it was analyzed by Mollen et al. who concluded that Dalton was indeed a dichromat but was a deuteranope rather than a protanope [2].

Dalton's theory that color deficiency was caused by a long-wavelength absorbing colorant in the fluids of his eyes ultimately proved to be incorrect. He was also not the first to "discover" color blindness. However, he made a substantial contribution to the understanding of color blindness through his meticulous observations, and he also inspired other scientists to study this fascinating phenomenon.

Atomic Theory

Although Dalton's name is indelibly associated with color deficiency, by far his most important work was in the area of atomic theory which he formally first published in 1805. The main points of Dalton's atomic theory were:

1. Elements are made of extremely small particles called atoms.
2. Atoms of a given element are identical in size, mass, and other properties; atoms of different elements differ in size, mass, and other properties.
3. Atoms cannot be subdivided, created, or destroyed.
4. Atoms of different elements combine in simple whole-number ratios to form chemical compounds.
5. In chemical reactions, atoms are combined, separated, or rearranged.

There is uncertainty about how Dalton arrived at his atomic theory [3]. Also, there was no evidence available at the time to scientists to deduce how many atoms of each element combine to form compound molecules so that Dalton, for example, wrongly assumed that water was composed of a single oxygen atom combined with a single hydrogen atom. Nevertheless, the essential features of his theory have survived to this day, and his theory can be said to be one of the bedrocks of modern chemistry.

Other Contributions

Dalton made notable contributions to meteorology (where he made over 200,000 observations, published several important essays on the gas laws (his law of partial pressures became known as Dalton's law), and wrote about rain, the color of the sky, and refraction).

indirectly from a sky of assumed or known luminance distribution to the illuminance on a horizontal plane due to an unobstructed hemisphere of this sky, where the contribution of direct sunlight to both illuminances is excluded [1].

Average Daylight Factor

The daylight factor provides the potential of the available daylight in interiors. It is defined as the ratio of the illuminance at a point in an interior room on a given plane due to the light received from a sky of a defined luminance distribution, excluding direct sunlight ($E_{\text{plane, room, CIE overcast}}$), to the illuminance on a horizontal plane in the open outside, without obstructions ($E_{\text{plane, outside, CIE overcast}}$). Usually, the CIE overcast sky and the horizontal plane are used as the standard situation. The daylight factor is expressed in percentages:

$$DF = 100 \cdot \frac{E_{\text{hor, room, CIE overcast}}}{E_{\text{hor, outside, CIE overcast}}}$$

Both the average daylight factor and the daylight factor distribution in the space are of interest. The average daylight factor is often a good predictor of the overall appearance of a room. Tregenza and Wilson [2] provided for offices a qualitative description of room appearance for different values of the average daylight factor (Table 1).

van Bommel Lighting Consultant, Nuenen, The Netherlands

Definition

Ratio of the illuminance at a point on a given plane due to the light received directly and

Daylight Factor, Table 1 Average daylight factor in offices with side windows and the corresponding visual character of the room

Average daylight factor	Room character	Effect of electric lighting
1%	Gloomy, harsh contrasts when viewing out	Electric lighting may mask daylight variation
2%	Areas deeper in the room may seem underlit	Appearance of daylit room even if electric lighting is the main illumination
5%	Looks brightly daylit; visual and thermal discomfort may occur with large window areas	Electric lighting rarely needed
10%	Looks like a semi-outdoor space; visual and thermal conditions may be unsuitable for office-type tasks	

Source: [2]

Average daylight factors between 2% and 5% usually correspond to acceptable to good visual conditions.

Graphical methods have been developed in the before-PC era to determine the daylight factor for buildings depending on their layout and fenestration. Today, most lighting calculation software packages, often available for free, can calculate daylight factors. A relatively good and useful approximation of the average daylight factor, at least for the critical range of daylight factors between 1 and 5, is obtained from the ratio of the sum of window areas and the sum of the surface areas of the room (floor, ceiling, and wall surfaces). Figure 1 (scale on the left) gives the correlation between daylight factors determined for many different situations and this area ratio [2].

It shows that the daylight factor can be predicted with high accuracy (for the range between 1% and 5%) with:

$$DF_{av} \approx \frac{40 \times \sum \text{Window areas}}{\sum \text{Room surface areas}}$$

Another, even more convenient predictor is the ratio of the sum of window areas and the floor area. The correlation, only slightly less accurate, is given in Fig. 1 with the scale on the right [2]. The predictor (again for the range between 0 and 5) is:

$$DF_{av} \approx \frac{8 \times \sum \text{Window areas}}{\text{Floor area}}$$

Some building standards use the ratio of window areas and floor area as a criterion to safeguard sufficient daylight entrance in buildings.

Daylight Factor, Fig. 1 Correlation between the average daylight factor of a room and the ratio of the sum of the window areas and the sum of the room surface areas (scale

on the left) and the ratio of the sum of the window areas and the floor area (scale on the right). (Source: [2])

Daylight Factor, Fig. 2 Daylight factor contours for an office of 5.4×3.6 m with window height and vertical position as shown in the figure and for surface reflectances for ceiling, walls, and floor of, respectively, 0.7, 0.5, and

0.2. At the bottom, the corresponding percentages of the time that more than 500 lux will be obtained are given for June and December (based on daylight measurements in Bratislava)

Daylight Factor at a Point

The daylight factor at a point in space gives information about the potential of daylight at different locations in a room. As an example, Fig. 2 gives an example of daylight factor contours for a typical one- or two-person office room. The daylight factor at a specific point in the room gives the daylighting potential of a building at that point for the poorest type of sky represented by the CIE standard overcast sky. What the actual illuminance at that point will be depends on the time of the day, the time of the year, and the actual location on earth (sun position). For some locations on earth, historical data is available on the probability that a given horizontal illuminance as a result of

skylight (excluding direct sunlight) is exceeded [3–5]. Figure 3 shows, as an example, a graph with such probability for Bratislava (geographical latitude approx. 48°N). Using the example of Bratislava, the daylight factors of the contours of Fig. 2 have been converted into percentages of the time that more than 500 lux horizontal illuminance is obtained in June and December, respectively, in Bratislava (values at the lower end of Fig. 2). Where in the summer month daylight can provide a substantial part of the required 500 lux, this is in the winter month impossible, even close to the windows. Of course, because of the sun’s position, at higher latitudes, lower lighting levels will prevail and at lower latitudes higher levels.

Daylight Factor, Fig. 3 The probability that a given horizontal illuminance due to skylight is exceeded in Bratislava in December and June, respectively; source, [4];

second horizontal scale, daylight factor (DF) required for an interior lighting level of 500 lux horizontally

Daylight Illuminants

Balázs Kránicz

University of Pannonia, Veszprém, Hungary

Definitions

Illuminants having the same or nearly the same relative spectral power distributions as phases of daylight.

Description of Daylight Phases

Originally, CIE standardized three illuminants for colorimetric purposes, illuminants A, B, and C. Illuminant C was the illuminant to represent

daylight. CIE also defined standard sources for these illuminants, and CIE standard source C was realized by using an incandescent lamp and some liquid filters. This source had, however, less radiation in the ultraviolet spectrum as natural daylight. With the increased use of optical brighteners, it became necessary to define daylight that came nearer to natural phases of daylight.

In the 1960s, the question how daylight power distributions of different correlated color temperatures could be calculated by a simple and explicit formula came to the front. The task was to determine relative spectral power distributions of daylight that could be measured on the surface of the Earth and was modified by the scattering and filtering effect of the sky.

Pioneer importance can be assigned to the publication of Judd, Wyszecki, and MacAdam [1]. The authors and their coworkers performed spectroradiometric measurements, and with proper extrapolation of the wavelength set of a number of observations, a data base was completed from 300 to 830 nm with 10 nm steps.

From the measurement data, the average spectral power distribution (in references mostly denoted by $S_0(\lambda)$) and two characteristic distributions ($S_1(\lambda)$ and $S_2(\lambda)$) were determined; see Fig. 1. The authors themselves called the method applied *characteristic vector method*, and it can be considered as a kind of *principal component analysis*. Of course, more than two characteristic vectors had been determined, but it was obvious that for a given chromaticity coordinate pair, the two abovementioned characteristic distributions could be used. (In principal component analysis, they belong to the two biggest eigenvalues of the covariance matrix of the data.)

Based on the mean vector $S_0(\lambda)$ and the two most important characteristic vectors or distributions, daylight power distribution $S(\lambda)$ of correlated color temperature T_{cp} can be calculated as follows:

$$S(\lambda) = S_0(\lambda) + M_1 \cdot S_1(\lambda) + M_2 \cdot S_2(\lambda). \quad (1)$$

Factors M_1 and M_2 in the formula above are not to be handled as constants; hence, these values

Daylight Illuminants, Fig. 1 The mean vector and the first two characteristic vectors to reconstitute spectral power distributions of daylight

depend on chromaticity coordinates x_D , y_D belonging to the given correlated color temperature T_{cp} :

$$M_1 = \frac{-1,3515 - 1,7703 \cdot x_D + 5,9114 \cdot y_D}{0,0241 + 0,2562 \cdot x_D - 0,7341 \cdot y_D} \quad (2)$$

and

$$M_2 = \frac{0,0300 - 31,4424 \cdot x_D + 30,0717 \cdot y_D}{0,0241 + 0,2562 \cdot x_D - 0,7341 \cdot y_D} \quad (3)$$

where in the case of $4,000 \leq T_{cp} < 7,000$

$$x_D = -4,6070 \cdot \frac{10^9}{T_{cp}^3} + 2,9678 \cdot \frac{10^6}{T_{cp}^2} + 0,09911 \cdot \frac{10^3}{T_{cp}} + 0,244063 \quad (4)$$

and in the case of $7,000 \leq T_{cp} \leq 25,000$

$$x_D = -2,0064 \cdot \frac{10^9}{T_{cp}^3} + 1,9018 \cdot \frac{10^6}{T_{cp}^2} + 0,24748 \cdot \frac{10^3}{T_{cp}} + 0,237040. \quad (5)$$

In both correlated color temperature ranges

$$y_D = -3,000 \cdot x_D^2 + 2,870 \cdot x_D - 0,275. \quad (6)$$

The unit of quantity of correlated color temperature T_{cp} in conditions of formula Eqs. 4 and 5 is kelvin (K). The form of Eqs. 4, 5, and 6 and the parameters in them come from curve fitting. The purpose of the curve fitting was to approximate the functional relation between correlated color temperature values and chromaticity coordinates of spectral power distributions of the measurement data set.

On the basis of the facts above, chromaticity coordinates, x_S and y_S , of $S(\lambda)$ determined by formula Eq. 1 have to match chromaticity coordinates x_D and y_D (from Eqs. 4, 5, and 6) belonging to correlated color temperature T_{cp} .

Nominal and Actual Temperature

The CIE recommended daylight illuminants in 1967. The correlated color temperatures are affected by the numerical value of the radiation constant c_2 . In accordance with the International Practical Temperature Scale, 1948, amended in 1960, which was in use at the time when the procedure for calculating daylight illuminants was adopted by the CIE, the value of c_2 was equal to $1,438\,0 \times 10^{-2} \text{ m} \cdot \text{K}$. With this value, the correlated color temperature of illuminant D65 was exactly equal to 6,500 K. The change of c_2 to the value of $1,438\,8 \times 10^{-2} \text{ m} \cdot \text{K}$ (International Practical Temperature Scale, 1968) increases the correlated color temperatures of illuminant D65 by the factor $1,438\,8/1,438\,0$. Thus, the correlated color temperature increases by approximately 4 K [2, 3].

A temperature value in the old scale is to be called *nominal temperature* (T_{nom}). Due to the change of constant c_2 , a temperature value belonging to some nominal temperature is called *actual temperature* (T_{act}) and can be calculated as

$$T_{act} = \frac{1,4388}{1,4380} \cdot T_{nom}. \quad (7)$$

Note that for the calculation of daylight illuminants or reproduction of definition tables of standards or CIE technical reports, the value of the actual correlated color temperature should generally be rounded to 3 decimal places after the decimal sign; see Table 1. If one wants to reproduce the spectra of daylight illuminants, the following hints should be applied besides that given for the rounding of the actual temperature:

Daylight Illuminants, Table 1 Nominal and actual correlated color temperature values of daylight illuminants

Daylight illuminant	Nominal correlated color temperature, K	Actual correlated color temperature, K
D50	5,000	5,002,782
D55	5,500	5,503,060
D65	6,500	6,503,616
D75	7,500	7,504,172

Daylight Illuminants, Fig. 2 Relative spectral power distributions of daylight illuminants belonging to different nominal correlated color temperature values

chromaticity coordinates at Eqs. 4, 5, and 6 have to be rounded to at least 6 decimal places, while factors M_1 and M_2 have to be rounded to exactly 3 decimal places – with the usual way of rounding.

Illustration of daylight illuminants belonging to different nominal correlated color temperature values is presented in Fig. 2.

Interpolation of Daylight Illuminants and Its Consequences

In the 1960s, spectroradiometric methods applied in colorimetry often achieved spectral data with a step size of 10 nm. Daylight illuminants had been defined with the same wavelength step. Later, as spectroradiometric methods improved, more and more demands arose to have daylight illuminants with smaller wavelength steps. As the original measurements could not have been repeated, the only way was to apply interpolation. First, distributions $S_0(\lambda)$, $S_1(\lambda)$, and $S_2(\lambda)$ were *linearly* interpolated for a wavelength step of 5 nm [4]. CIE recently published a technical report that recommends nonlinear interpolation and gets to smooth spectral distribution curves [5].

In order to get the appropriate spectral power distributions and chromaticity coordinates, some recommendations contain certain rounding rules for computing M_1 and M_2 ; hence, using *other wavelength steps* than the original one of 10 nm, minor differences arise between chromaticity coordinates belonging to correlated color temperature values (x_D , y_D); see Eqs. 4, 5, and 6) and chromaticity coordinates (x_S , y_S) computed from daylight spectral power distributions themselves (from Eq. 1). These differences do not influence practical applications, but they are very embarrassing from a theoretical point of view. This anomaly had not been explained till 2000 [6].

CIE Standard Illuminant D65 (Shortly CIE D65)

As discussed in the previous section, the detailed spectrum of CIE standard illuminant D65 was calculated from the fixed 10 nm values by linear interpolation. Data can be found, e.g., in the book by Wyszecki and Stiles [7] and in the standard for CIE standard illuminant A and D65 [8]. The tabular data were rounded in such a way that 6 significant decimal places were kept, together with the

integer part and the digits of the decimal fraction. It should be noted that an unusual rounding rule had been applied: if a number ended with the digit 5, it was rounded downwards, e.g., at 405 nm the piece of data 87,12045 was rounded to 87,1204.

CIE D65 is one of the most important and most frequently used standard illuminants of the CIE. Many spectrophotometers indicate color values of surfaces in such a way as if they had been illuminated by CIE D65; for further details, see Chapter CIE Standard Illuminants and Sources.

CIE D50, D55, and D75

Although CIE suggests using D65 whenever it is possible, three further illuminants are often used. These illuminants are D50, D55, and D75. D50 is often used in graphic arts; D55 and D75 correspond to phases of daylight when the Sun starts setting and when the blue sky dominates, respectively.

The calculation of D50, D55, and D75 can be performed similarly to that of D65. The definition table in publication CIE 15:2004 [5] contains the wavelength range 300–780 nm with a step size of 5 nm. It should be noted that in this table all

numerical data were rounded to 3 decimal places with the usual rounding rule, independently from the number of digits of the integer part of the values.

Recalculation of Daylight Illuminants

The original CIE rule to calculate the spectra of daylight illuminants is that first the spectrum for the 10 nm steps has to be determined and this spectrum has to be linearly interpolated. If one tries to interpolate first the S_0 , S_1 , and S_2 functions, one will get slightly different values.

It turned out that no rounding rules would give a perfect solution for eliminating the problem of differences between chromaticity coordinates calculated by Eqs. 4, 5, and 6 and from the illuminant itself (Eq. 1). It was found that factors M_1 and M_2 in Eq. 1 depend on the wavelength step of distributions or characteristic vectors S_0 , S_1 , and S_2 . Factors M_1 and M_2 were originally determined for the case of a wavelength step of 10 nm. If any type of interpolation of daylight illuminants is applied, this fact leads to computational inaccuracies and theoretical contradictions.

Daylight Illuminants, Fig. 3 Spectral power distributions of D50, D65, ID50, and ID65

Consequently, factors M_1 and M_2 in Eq. 1 have to be *recalculated* in every case when the wavelength step of distributions S_0 , S_1 , and S_2 differs from 10 nm.

A mathematical procedure was worked out by which factors M_1 and M_2 can precisely be recalculated for any case of interpolation of S_0 , S_1 , and S_2 [6]. Based on the recalculation chromaticity coordinates (x_D , y_D) depending on the correlated color temperature of daylight, distributions always match those, (x_S , y_S), calculated from distribution S . CIE publication 204 contains Excel sheets to perform calculations for any correlated color temperature [5].

Indoor Daylight Illuminants

All daylight illuminants dealt with above have power also in the UV range that cannot be neglected in the case of fluorescent samples. However, natural situations like applying daylight filtered by a window sheet raised a demand for having some indoor versions of daylight illuminants. CIE's technical committee TC 1-66 investigated several plate glass types. Based on their spectral transmittance properties and average thickness, two indoor daylight illuminants were defined: ID50 and ID65 [10]. Figure 3 illustrates D50, D65, ID50, and ID65.

Definition

Daylight is the totality of visible radiation originating from the sky and, when visible, the sun during the hours of daytime.

Introduction

The colors or, more specifically, the spectra of the various phases of daylight are closely related to the commonplace experience of naturally occurring sun and sky conditions, e.g., clear blue skies, white clouds, and red sunsets. Prevailing conditions can be characterized in terms of a correlated color temperature. For certain typical sun and sky conditions, there are standardized spectral power distributions. From these it is possible to estimate the time-varying spectra of daylight from illuminance values in standardized climate data files. Thus, it becomes possible to predict the daylight spectra experienced by building occupants. This has found application in studies on the nonvisual effects of daylight and the performance of dynamic glazing systems.

The qualitative aspects of the colors, or hues, of daylight are difficult to describe, harder still to codify in any but a superficial manner. Intricately bound with these perceptions are the conditions under which they occur:

- Prevailing degrees of sunniness and cloudiness
- The position of the sun in the sky (when visible)
- Clearness or haziness of the skies
- Occurrence of various cloud types
- Properties of the natural and man-made reflecting environment

Each of these can have some notion of colors associated with it. How daylight can appear to humans found expression in the world of art where certain qualities of illumination became associated with specific locales, for example, the subtle hues in the gently luminescent skies (often reflected over water) painted by the Dutch masters of the seventeenth century or the bright, vivid shades used by Cezanne and fellow painters who sought inspiration in the sun-drenched south of France. Commonplace holiday photographs can also reveal much of the variety in experienced daylight conditions, both in natural and man-made settings, Fig. 1.

Notwithstanding the evident variety in the hues of the experienced luminous environment,

consideration of the color of daylight has not generally played a role in the daylighting design of buildings – at least not until very recently. In purely aesthetic terms, the color of the daylight is easily noticed, e.g., the warm light from a low sun, the cool light in rooms that are sunless, etc. As a consequence, rooms with a southerly aspect may, in a general rather than just a lighting sense, be perceived as “warm” and those with a northerly aspect as “cool.” This is particularly so in higher-latitude locations, e.g., the Scandinavian countries where the sun is often low in the sky [1]. Designers may even try to compensate somewhat for this, at least for the rooms with a northerly aspect, by selecting paint finishes/decor with warm hues to neutralize somewhat the perception of coolness in the space. There is however little in the way of an empirically based approach to systematically apply such considerations to the color design of spaces.

While it is possible to describe the various types of daylight that occur using chromaticity coordinates [2], it is often simpler and indeed more revealing to consider the spectral power distribution (SPD) of the light rather than reducing it to derived quantities which could hide important details. Recent advances in variable transmission glass technology [3] and in understanding the basis of the nonvisual effects of daylight [4] further suggest that daylight SPDs rather than chromaticity coordinates are needed to progress in these areas. Thus, this chapter will describe daylight and its interactions – reflection and transmission – using spectra rather than any of the color systems. It begins with a consideration of the spectrum of solar radiation arriving at the top of the Earth’s atmosphere.

The Standard Solar Spectrum

The visible radiation is only a part of the total energy associated with daylight radiation. The full spectrum of radiation ranges from about 300 to 4,000 nm, i.e., from the near ultraviolet to the far infrared (both invisible to the eye). The radiation from the sun arriving at the Earth, but before entering the atmosphere, is called extraterrestrial radiation. It approximates a black body radiator with a temperature of 5,800 K, i.e., a

Daylighting, Fig. 1 The “colors” of daylight – light from the sun and/or sky together with that reflected by the environment

large “tail” at long infrared wavelengths gradually diminishing to zero, the peak of output in the visible spectrum, and a steep cutoff at ultraviolet wavelengths, Fig. 2. How that energy arrives at the surface of the Earth depends on various factors including atmospheric.

Scattering of sunlight in the atmosphere by air, water vapor, dust, etc. gives the sky the appearance of a self-luminous hemispherical source of light. Sunlight is commonly referred to as direct light since it appears to originate from a small source and can cast sharp shadows. The sky however is an extended source of illumination that casts only soft shadows, and so skylight is commonly referred to as diffuse light. Scattering of solar radiation in the atmosphere does not occur equally across the visible spectrum – shorter, i.e., blue wavelength light is scattered more than the

other colors. Thus, on clear days, the sky appears blue – the observer is seeing light (originating from the sun) that arrives via indirect scattered paths. For the same reason, the sun appears yellow because blue light has been scattered out of the beam, i.e., the direct path from the sun to the observer. The lower the angle that the sun appears in the sky, the greater the distance in the atmosphere through which the sunlight travels. Thus, more of the blue (and green) wavelengths are scattered out of the beam, and the sun appears progressively yellow, orange, and then red as the sun sets. A blue sky and a red sunset are in fact the same optical phenomenon – preferential scattering of short wavelength light in the atmosphere – seen from two different viewpoints, Fig. 3. The air mass for a horizontal view (at sea level) is taken to be 38. Thus, the beam of light from the sun at the

Daylighting,

Fig. 2 Standardized extraterrestrial radiation with direct and global radiation received at the surface of the Earth (air mass = 1.5)

Daylighting, Fig. 3 A blue sky and a red sunset – two different views of the same phenomenon

horizon has traveled through approximately 25 times more atmosphere than when seen at an altitude of 41.8° (i.e., the condition for AM1.5).

The Standard Daylight Illuminants

The standard solar spectra were largely created for the simulation and testing of energy systems, e.g., photovoltaic panels. Similarly, the standard daylight (or D) illuminants were formulated by the International Commission for Illumination (CIE) to represent various “phases of daylight” [5]. Three of the most commonly used standard D illuminants are D55, D65, and D75. The normalized spectral power distribution (SPD) for each of this is shown in Fig. 4. Also plotted is the visual sensitivity curve $V(\lambda)$ – each curve has been normalized to have the same value at 555 nm. The illuminants are characterized by their nominal correlated color temperature (CCT), i.e., the temperature of the Planckian or blackbody radiator whose perceived color most

closely resembles that of a given stimulus at the same brightness and under specified viewing conditions. The nominal correlated color temperatures for D55, D65, and D75 are, respectively, 5,500 K, 6,500 K, and 7,500 K. The illuminant SPD curves also exhibit the absorption features present in the “direct” and “global” spectral irradiance curves (Fig. 2), though they are now easier to see with the smaller range in plotted wavelength.

In relative terms compared to D65, illuminant D55 will appear “warmer” and D75 “cooler.” Note that higher correlated color temperatures (CCTs) result in SPDs that are perceived as progressively “cooler,” that is, “bluer” even though the (equivalent) blackbody radiator is of course hotter. Of these three, illuminant D65 is taken as the reference source for daylight, corresponding roughly to the illumination from midday sun and (blue) skylight in temperate European locations:

Daylighting,
Fig. 4 Standardized
daylight illuminants and the
visual sensitivity curve

Daylighting, Table 1 Correlated color temperatures for various daylight sources. (Source: Kodak)

Daylight source	CCT
Sunlight – sunrise or sunset	2,000 K
Sunlight – 1 h after sunrise	3,500 K
Sunlight – early morning	4,300 K
Sunlight – late afternoon	4,300 K
Average summer sunlight at noon (Washington, DC)	5,400 K
Direct midsummer sunlight	5,800 K
Overcast sky	6,000 K
Average summer sunlight (plus blue skylight)	6,500 K
Light summer shade	7,100 K
Average summer shade	8,000 K
Summer skylight	9,500–30,000 K

CIE standard illuminant D65 is intended to represent average daylight and has a correlated colour temperature of approximately 6,500 K. [6]

Daylight and Correlated Color Temperature
Data relating natural illumination conditions to correlated color temperatures is sparse. One of the most comprehensive sources of data is the Kodak Cinematographer’s Field Guide [7]. It gives equivalent correlated color temperatures for 11 daylight conditions, Table 1. Here the daylight condition for the nominal CCT of 6,500 K (i.e., D65) is described as “average summer

sunlight (plus blue skylight),” essentially equivalent to the arguably less precise CIE description of the daylight conditions.

Note that the CCT for sunlight varies from 2,000 (sunrise/sunset) to 5,800 K, with “average sunlight at noon” having a CCT of 5,400 K. Thus, illuminant D55 can be assumed to represent the SPD for (direct) sunlight provided that the sun is not too low in the sky. In reality, average summer sunlight plus blue skylight will in fact be a combination of SPDs – D55 for sunlight and some (currently unspecified) SPD for blue skylight with a CCT of up to 30,000 K. The reference illuminant D65 is therefore a compromise offering an SPD that, for most practical purposes, is equivalent to some combination of D55 (sunlight) and some unspecified high CCT for blue skylight. The reference daylight illuminant CCT of 6,500 K is closer to the CCT for average sunlight (5,500 K) than the $\geq 9,500$ K for blue skylight because, in most situations, illumination from the sun (direct and reflected) will dominate that from the sky.

Kodak recommends that an overcast sky has an SPD equivalent to a CCT of 6,000 K. In which case, it would appear that the closest match of the three D illuminants is either D55 or D65. Given that D55 is believed to be a good match for sunlight, the SPD for an overcast sky is better represented by D65. That has been confirmed by measurements taken on a wide range of commonly occurring overcast sky conditions [8].

Daylight Quantities in the Standard Climate Datasets

The quantitative nature of illumination from the sun and sky for any particular locale can be appreciated by examining the luminous output from both the sun and the sky over a period of a full year. A full year is needed to capture seasonal variation in daylight. The principal sources of annual data for daylight are the standard weather files which were originally created for use by dynamic thermal modeling programs [9]. These datasets contain averaged hourly values for a full year, that is, 8,760 values for each parameter. The key daylight parameters stored in the weather files are the diffuse horizontal illuminance and the direct normal illuminance. The diffuse horizontal illuminance is the visible light energy from the unobstructed sky that is incident on a horizontal surface. The direct normal illuminance is the visible light energy from the sun that is incident on a surface which is kept normal to the beam of radiation, i.e., the photocell always “points” directly to the sun. The illuminating power of the sun is measured in this way because when the sun is low its contribution to horizontal illuminance is small even if the absolute intensity is high.

A visualization of the illuminance data from the standard weather files for Madrid (Spain) and Ostersund (Sweden) is given in Fig. 5. The time-series data of 8,760 values has been rearranged into an array of 365 days (x-axis) by 24 h (y-axis). The shading at each hour indicates the magnitude of the illuminance – see legend – with zero values shaded gray. Presented in this way, it is easy to appreciate both prevailing patterns in either quantity or their short-term variability. Most obvious is the daily/seasonal pattern for both illuminances: short periods of daylight in the winter months and longer in summer. The hour-by-hour variation in the direct normal illuminance is clearly visible, though it is also present to a lesser degree in the diffuse horizontal illuminance (i.e., light from the sky).

Comparing the data for the two locales, one immediately notices the pronounced seasonal variation in day length for Ostersund, which is in the north of Sweden. As might be expected, the Madrid data show many sunny days, especially

in summer. Note that Spain uses Central European Time despite having a longitude similar to the UK. Thus, there is a marked divergence between clock and solar time in the Madrid data. The diffuse horizontal illuminance reaches a maximum of about 40,000 lx (red shading), and direct normal illuminance under clear sky conditions often exceeds 70,000 lx (yellow shading). This is so for both locales. During winter in northern Sweden, the diffuse horizontal illuminance is typically 5,000 lx or even less, with few hours of sun.

Both diffuse and direct illuminances will, in reality, vary over periods much shorter than an hour. Interpolation of the dataset to a time-step shorter than 1 h will provide a smoother traversal of the sun, which may be necessary when using the data for simulation of daylight. Interpolation alone however will not introduce short-term variability into the values for diffuse horizontal and direct normal illuminance. The patterns of hourly values in the illuminance datasets are unique, and because of the random nature of weather, they will never be repeated in precisely the way shown in Fig. 5. Climate datasets are however representative of the prevailing conditions measured at the site, and they do exhibit much of the full range in variation that typically occurs, i.e., they provide definitive yardstick quantities for modeling purposes. These datasets are used to define the external conditions for climate-based daylight modeling (CBDM), i.e., the prediction of annual profiles of internal (daylight) illuminance due to all the unique sun and sky conditions derived from a standard climate file [10].

For every value in the datasets for diffuse horizontal and direct normal illuminance, it is possible to estimate, with varying degrees of reliability, a corresponding CCT using the entries in Table 1. For example, much of the intense sunlight (i.e., direct normal illuminance) could be taken to have a CCT of around 5,400–5,800 K. Thus, the SPD for the sunlight could be approximated to standard illuminant D55. Sunlight around the hours of dawn and dusk could be assigned lower CCTs, e.g., 2,000–3,500 K, while early-morning and late-afternoon sun could be approximated to a source with a CCT of 4,300 K. Use of climate files to estimate the SPD of the sun and skylight

sources of illumination has recently been demon-
strated for the purpose of modeling the nonvisual
effects of daylight (see section “[The Nonvisual
Effects of Daylight](#)”).

Sky Models

A sky model is a mathematical equation that
describes the variation in luminance across the
hemispherical sky vault. The simplest possible

Daylighting,

Fig. 6 Simulated 180° hemispherical “fish-eye” images of a constant chromaticity clear sky distribution (a) and a variable chromaticity clear sky (b)

model describes a sky of uniform luminance, i.e., the same brightness is seen wherever one looks above the horizon (in an unobstructed setting). At the start of the twentieth century, it was believed that overcast skies exhibited only moderate variation in brightness across the sky dome, and so they could be considered to be of constant (i.e., uniform) luminance. Measurements revealed however that a densely overcast sky exhibits a relative gradation from darker horizon to brighter zenith; this was recorded in 1901. With improved, more sensitive measuring apparatus, it was shown that the zenith luminance is often three times greater than the horizon luminance for some of the most heavily overcast skies [11]. The formulation for the luminance pattern of overcast skies presented by Moon and Spencer in 1942 was adopted as a standard by the International Commission for Illumination (CIE) in 1955.

The equations describing the luminance pattern for clear or intermediate skies are rather more complex than that for the CIE standard overcast sky. The complexity arises from a number of observed effects that are accounted for in the model. Among these are a bright circumsolar region, a sky luminance minimum that is at some point above the horizon, and a brightening of the sky near the horizon. The scales of these effects are related to the solar position and the relative magnitudes of the illumination produced by the sun and sky [12]. These and similar sky models, e.g., the Perez all-weather model [13], do not include provision in the formulation for any variation in chromaticity of the luminance across

the sky vault. If the sky color is required in a daylight simulation, the RGB radiance values applied to the self-luminous “material” used to model the sky can be set to achieve the desired effect, e.g., a small blue “excess” to create a blue hue for the clear sky distribution, Fig. 6a. Notwithstanding the variation in luminance across the sky vault, the chromaticity will remain constant.

More recently, sky models with varying chromaticity have been formulated to depict the subtle color gradations seen in nature [14]. Based on analytical models for the scattering of light in the atmosphere, these formulations can account for effects such as blue sky at high altitude together with warm (i.e., blue deficient) sky just above the horizon, Fig. 6b. It should be noted that data to validate these models is scarce, and, for daylight simulation, their use is primarily to lend realism to renderings rather than for any quantitative modeling, e.g., illuminance prediction.

Daylight in Buildings

Daylight illumination of a space can be considered as a series of transforms – from a light emitted by the luminous source(s) to that received at a point in a space. For daylight performance evaluation, practitioners have largely been concerned with the amount of light received at a point in a space (i.e., lux levels) and have not been concerned with the spectral nature of any of the transforms. For most quantitative modeling purposes – using either the long-standing daylight

factor method or more recent climate-based daylight modeling – it is sufficient to describe all opaque surfaces as gray reflectors. And, although tinted glazing materials may be represented in the simulation by their RGB spectral transmittance values, an equivalent gray transmittance would work just as well.

Color can, of course, be modeled in a lighting simulation. Though, depending on the tool used, there may be limitations or restrictions to the degree of precision that can be achieved when modeling the spectral properties of reflection and transmission. Key among these are the limitations of having three channels, as is the case with *Radiance* – generally considered the most widely used and rigorously validated lighting simulation package [15]. The “color” assigned to each of the three channels is arbitrary, though in most instances they are used to model the standard RGB trichromatic system common in computer graphics and digital image display technology. While adequate for many if not most image display purposes, the three channel RGB approaches are in fact a fairly coarse representation of the reflection and transmission properties of materials. For example, it is possible to have materials with (noticeably) different spectral reflectance curves giving the same RGB values [16]. Thus, although noticeably different to an observer, they would all have the same representation in the simulation, i.e., the same RGB spectral reflectance values.

Transformation of Daylight by Reflection and Transmission

Considering only the normalized spectra (i.e., ignoring absolute values), one can represent the transformations fairly simply as follows. Consider a space with a window receiving direct sun on sunny day with a clear blue sky. The SPDs for the sunlight and the skylight incident on the window are denoted, respectively, by the vectors $\mathbf{D}^{\text{sun}}$ and $\mathbf{D}^{\text{sky}}$. The SPD for the light received at the window will be comprised of these two illuminants plus sunlight and skylight reflected off the external surfaces, e.g., the ground and nearby buildings. The vector for the reflected SPD incident on the window is denoted by $\mathbf{D}^{\text{ref}}$. The reflected SPD will be some combination of the SPDs from the

sky and (if present) the sun, modified by the spectral reflectance properties of the ground, external buildings, etc. The SPD for the light incident at the window $\mathbf{D}^{\text{icd}}$ is given by:

$$\mathbf{D}^{\text{icd}} = \mathbf{D}^{\text{sun}} + \mathbf{D}^{\text{sky}} + \mathbf{D}^{\text{ref}} \quad (1)$$

If, say, the window is facing the sun direction, then of the total light incident on the glass that arriving directly from the sun will probably form the greatest part. And so the incident SPD could be approximated to the D55 illuminant. As noted previously, only the shape of the spectra is important for this illustration.

The spectrum of light incident on the window will, on passing through it, be modified by the spectral transmittance $\mathbf{T}^{\text{glz}}$ of the glazing material. The element-by-element (or Hadamard) product of the incident SPD and spectral transmittance vectors give the SPD for the light entering the space:

$$\mathbf{W}^{\text{ill}} = \mathbf{D}^{\text{icd}} \circ \mathbf{T}^{\text{glz}} \quad (2)$$

The vector $\mathbf{W}^{\text{ill}}$ may be called the window illuminant SPD since this is the daylight from the window illuminating the space. This light can arrive at a point in the space directly (if the point can “see” the window) and indirectly following one or more reflections. The SPD of the window illuminant will in turn be transformed following every possible reflection in the space depending on the spectral reflectance properties of the various surfaces. Thus, for every point in the space (x, y, z, θ, ϕ) , the light falling on it $\mathbf{P}^{\text{ill}}$ will have a unique SPD comprised of direct and reflected SPDs:

$$\begin{aligned} \mathbf{P}^{\text{ill}}(x, y, z, \theta, \phi) &= \mathbf{W}^{\text{ill}}(x, y, z, \theta, \phi) \\ &+ \mathbf{W}^{\text{ref}}(x, y, z, \theta, \phi) \end{aligned} \quad (3)$$

In addition to the (x, y, z) position in the space, the orientation of the receiving surface (θ, ϕ) needs to be defined also – the “surface” could be the eye of an observer. If the surface cannot “see” the window directly, then the $\mathbf{W}^{\text{ill}}(x, y, z, \theta, \phi)$ term will be zero. This process of spectral transformations is illustrated in Fig. 7.

Daylighting, Fig. 7 Transformations in the SPD from source(s) to a point inside a space

Practical Simplifications

Under many actually occurring conditions, the SPD of (visible) radiation incident on the windows of a building in a man-made setting can be assumed to be dominated by light from the sky and sun (if present). Thus, one can neglect the transform in the SPD from the reflected component because (a) the ground reflectivity is invariably low and (b) man-made external surfaces in any case tend to be fairly neutral in color. Under these conditions, it is reasonable to assume that the SPD incident on the windows will be approximately that of the dominant source. For example, if direct sun is incident on the window of a building, we can assume that the incident SPD is that of the standard illuminant D55, i.e., $D^{icd} = D^{55}$.

In an actual building with typical neutral decor, the SPD is likely to vary only marginally with position in the space. In other words, inside the space the window illuminant SPD is not transformed significantly on reflection. One can make the approximation that $W^{rf} \simeq W^{ill}$ since the variation with position (x, y, z, θ, ϕ) in the space is not a significant factor. Thus, one can assume that the (normalized) SPD at any point in the space is

approximately equal to the SPD of the light entering the space through the window, i.e., $P^{ill} \simeq W^{ill}$.

Combining these two simplifications, the SPD of light in the space (P^{ill}) is now governed by just two factors: the SPD of the incident light and the spectral transmittance of the glazing. Using the above example with direct sun incident on the window, the equation for the SPD in the space simplifies to:

$$P^{ill} \simeq D^{55} T^{glz} \quad (4)$$

This approximation has been tested and shown to be perfectly adequate for the purpose of predicting the SPD in a space (see section “[Variable Transmission Glazing](#)”).

Measured Daylight Spectra

It is now possible to take reliable measurements of SPDs using relatively inexpensive, handheld spectrometers. These devices measure spectral irradiance, which is approximately that seen by the eye when “pointing” in the same direction. Four measured daylight SPDs are shown in Fig. 8. The inset

Daylighting, Fig. 8 Measured daylight spectra: (a) blue sky, (b) sunlit garden, (c) back of a room with warm/neutral decor and clear glazing on a bright day, and, (d) daylight from a stained glass window

photograph shows approximately what was “seen” by the sensor, and the visual sensitivity curve $V(\lambda)$ is also shown. The SPDs were normalized against $V(\lambda)$ to have the same area in each case, i.e., to have the same lux value irrespective of the shape of the spectra. This allows a like-for-like comparison of the SPDs whatever their absolute values are.

Two Outdoor Daylight Spectra

The SPD for light from the bluest part of a clear sky shows pronounced peaks around 400 nm, Fig. 8a. Comparison with the standard illuminants (Fig. 4) indicates some similarity on the basic form; however, this light would have a CCT significantly higher than the 7,500 K for $D75$ (the spectrometer reported a CCT of over 12,000 K for this SPD). The SPD for the sunlit garden shows a strong peak in the green part of the spectrum due to reflection from the foliage and a steep rise at around 700 nm at the start of the infrared region, Fig. 8b.

Two Indoor Daylight Spectra

The SPD taken “looking” at the back of a daylighted room with warm/neutral decor and clear glass windows is shown in Fig. 8c. The measurement was taken on a sunny day, and, although there was no direct sun in the space at that time, the SPD incident on the window would probably have been dominated by reflected sunlight. The decor in the space would be described as warm/neutral since there are no highly saturated colors present. The SPD is fairly flat over most of the visible range, and the illumination in the space would indeed be described as essentially neutral. In the range of 600–700 nm, it is possible to discern some of the features present in the standard illuminants (Fig. 4). Note however that the SPD for daylight indoors cannot in the main correspond to $D65$ because all standard glass materials absorb light at short wavelengths.

The SPD for the light from the stained glass window is perhaps rather more neutral than one might expect from the photograph of the window, Fig. 8d. The visual impression of the window

suggests that greens and yellows will be dominant in the SPD. However, for the window as a whole, the bulk of the light transmission occurs through the clear sections of the glass, resulting in a fairly neutral spectrum overall. This is because the tinted glass has a lower transmission than clear glass. The more saturated the color of the stained glass, the lower its transmission, and so the smaller its contribution to overall illumination. Notwithstanding the striking visual impression made by stained glass windows, the overall SPD of the light through them can be surprisingly neutral provided that a proportion of the glass in the window is clear.

Applications

Perhaps the first practical application of the science of daylight color was in the field of cinematography, where the various phases of daylight were associated with a correlated color temperature (see Table 1). In moviemaking, one scene could take several days to film, and if done so under natural lighting, it is important to maintain color consistency between the various “takes.” Cameramen can use subtle filters, or film stock with different spectral sensitivities, to help maintain a desired CCT between “takes” filmed on days with different daylight conditions [7]. Filming indoors was largely carried out under artificial lighting. Thus, any consideration of the color of daylight indoors was largely an aesthetic concern [1].

However, recent advances in:

- (i) understanding the basis for the non-visual effects of daylight; and,
- (ii) the manufacture of variable transmission glazing,

have caused scientists and practitioners to pay attention to the color, or more specifically, the spectra of daylight experienced indoors by the occupants of buildings. The sections below describe some of the first studies to model (section “[The Nonvisual Effects of Daylight](#)”) and measure (section “[Variable Transmission](#)

[Glazing](#)”) daylight spectra for the two application scenarios noted above.

The Nonvisual Effects of Daylight

It is now well recognized that illumination received at the eye is responsible for a number of effects on the human body that are unrelated in any direct sense to vision. Light has measurable neuroendocrine and neurobehavioral effects on the human body, in particular with respect to maintaining a regular sleep-wake cycle that is entrained to the natural diurnal cycle of night and day [17]. Additionally there is evidence to suggest links between daylight illumination in particular and alertness, productivity, and academic achievement [18]. In the early 1990s, it was discovered that the eye possesses an additional non-rod, non-cone photoreceptor named photosensitive retinal ganglion cells or pRGCs [19]. The pRGCs communicate light-induced signals to the suprachiasmatic nuclei (sometimes referred to as the “circadian pacemaker”) in the anterior hypothalamus of the brain. This and related discoveries have led to the emergence of a new area for photobiology research concerned with daylight/light exposure and its nonvisual effects [20].

There are numerous factors operating in a building that influence the sense of well-being or, otherwise, that an occupant experiences. Daylight is known to be one of them. The emergence of the field of photobiology has led to the speculation that we might one day be able to predict for an interior space a measure of the nonvisual effect of the daylight provided by the design of the building. This speculative measure has been referred to as the “circadian potential” or “circadian efficiency” of the space [21].

The spectral sensitivity of the photosensitive retinal ganglion cells is shifted to the blue compared to the visual sensitivity $V(\lambda)$ curve. The precise shape is not known, but the peak of sensitivity is around 460–480 nm. The timing, intensity, spectrum, duration, pattern of light received at the eye, and prior light history are the principal factors determining entrainment of the circadian cycle. Although the understanding of the various factors, and their interrelations, is incomplete,

there is now sufficient empirical data to begin to experiment with predictive models for the non-visual effects of light – artificial as well as daylight [22]. With regard to the spectrum of light received at the eye, for two sources of illumination delivering the same lux value, one that has a blue-rich SPD could produce a stronger nonvisual effect than one which has less power in the 460–480 nm region [23]. Thus, any materials that significantly transform the spectrum of daylight entering a space should, once the scientific basis is sufficiently refined, be assessed for their potential to maintain desired nonvisual effects in addition to providing illumination for task.

Variable Transmission Glazing

The use of daylight in office buildings is generally considered to be a greatly underexploited resource. In large part this is because of the highly variable nature of daylight illumination. The natural, large variability in daylight means that users will often need to use shades to moderate excessive ingress of daylight. Most shading systems act as a “shutter” that is either open or closed, with users rarely making the effort to optimize the shading for both daylight provision and solar/glare control. And blinds are often left closed long after the external condition has changed. A glazing with a transmissivity that varies continuously between clear and dark extremes could offer a much greater degree of control over the luminous environment.

The principle behind variable transmission glazing (VTG) is straightforward: the transmission properties of the glazing are varied to achieve an “optimum” luminous and/or thermal environment. In practice, developing the technology has proven challenging. Of the various VTG formulations undergoing research and development over the last two decades, the most promising appears to be electrochromic where a small applied voltage varies the transmission properties of the glass [24]. One of the most advanced of these materials is produced by SAGE Electrochromics Inc., and in 2013, it started being manufactured in high volume. This EC glass varies in visible transmission from 60% when in the clear state down to 1% (or even less) when fully tinted. As the glass

darkens (i.e., “tints”), the longer wavelengths are diminished proportionally to a greater degree than the shorter wavelengths, giving the EC glazing good solar control properties to help prevent overheating. Optically, the consequence of this is to shift the peak in visible transmission to the blue end of the spectrum. However, while control of the luminous and thermal environment is highly desirable, occupants are believed to prefer daylight illumination that is perceived as neutral rather than tinted. Thus, the question regarding the neutrality of the illumination spectrum is an important one that needs to be addressed.

Effectively neutral illumination in spaces with EC glass can be achieved provided that a proportion of the glass remains in the clear state [25]. This was demonstrated by taking measurements of the SPD of ambient illumination in a daylighted office with EC glass under sunny conditions. The measurements were compared with a theoretical model for the predicted SPD. The theoretical SPD for the illumination in the space was predicted using the simplified expression in Eq. 4. Of the eight EC panels in the window of the office used for the evaluation, five were set to full tint and three were in the clear state [26]. The spectral transmittance of the eight glass panels in the various states was calculated as a composite spectral transmittance curve based on the individual spectral transmittance curves and their proportions. Thus, in terms of the SPD, the eight panels in the various states were modeled as a single entity.

The measured SPDs were taken at six points in the office: four corresponding to the view positions of the four occupants who normally work in this space, one at the back of the office looking toward the window, and one at the window looking toward the back of the space. The six measured SPDs (normalized as before) are shown in Fig. 9. Notwithstanding the fact that the SPDs were measured at different points across the room – both looking toward and away from the window – the SPDs are in fact very similar. Furthermore, the SPDs are fairly neutral across the visual range, and the $V(\lambda)$ curve is also shown. This is consistent with experience of such spaces where the illumination turns out to be rather more neutral than one might expect from

Daylighting, Fig. 9 Theoretical and measured SPDs for an office with electrochromic glazing – with photographs of the EC window (*upper*) and the rear of the space (*lower*)

the visual impression of the window – provided that a proportion of the glass is clear. Compare this with the illumination SPD for daylight through the stained glass window (Fig. 8d), where a similar effect is observed. Also shown in Fig. 9 is the predicted SPD calculated using the D55 illuminant and a spectral transmittance properties of the composite [27]. The agreement is remarkably good, and, while these are results from a single study, they provide encouragement for wider and deeper investigations of daylight SPDs experienced by the occupants of buildings.

The Future

The daylighted indoor luminous environment can be quite different to that experienced outdoors. Appreciation of the recently discovered nonvisual effects of illumination has led to a reconsideration of the function of daylight in buildings. The quantification and evaluation of the spectral nature of daylight experienced by building occupants are now achievable using fairly modest apparatus. In the immediate future, it is likely that there will be efforts to characterize the daylight experienced indoors in terms of both the spectrum received at the eye and also the absolute (visual) magnitude of

the illumination delivered for task. When the relation between daylight and nonvisual effects becomes better understood, practitioners will then have a basis to refine the appreciation of what constitutes “sufficiency” for daylight provision. That may have far-reaching consequences for the drafting of future standards for daylight in buildings.

Halftone layer superposition equations

Definition

In color halftoning, the Demichel equations define the relationships between the surface coverages of the printed ink dots and the surface coverages of the Neugebauer primaries, i.e., the surface coverages of the colorants populating the color image. These equations are valid for the independently laid out ink layers that occur in stochastic screening, in error diffusion halftoning, and in mutually rotated clustered dot or line screens. The Demichel equations are used in connection with spectral models predicting the reflectances of color prints in function of the deposited amount of inks [1, 2].

Overview

Professional as well as desktop printers are either able to print with a limited number of pixel dot sizes or with a single pixel dot size. For example, in modern ink-jet printers, several droplets may be printed at the same pixel location, leading to a limited number of pixel dot sizes. In classical offset prints, a pixel location is either printed at a fixed size or remains unprinted. Color variations are created by halftoning, i.e., by creating with the different colored inks halftone dots having predetermined surface coverages.

For the sake of clarity, let us consider a cyan, magenta, and yellow ink print halftoned with classical mutually rotated halftone dots. As shown in Fig. 1, the superposition of ink dots of different colors yields new colors. The superposition of a cyan and a yellow ink dot yields a green dot portion; the superposition of a cyan and a magenta ink dot yields a blue dot portion; the superposition of a magenta and a yellow ink dot yields a red dot portion; and the superposition of a cyan, a magenta, and a yellow dot yields a black dot portion. Like in a puzzle, the space of a color halftone comprises juxtaposed dot portions of the colors white (no ink), cyan (cyan only), magenta (magenta only), yellow (yellow only), red (magenta superposed with yellow), green (cyan

Demichel Equations, Fig. 1 (a) Clustered dot color halftone with the *cyan* layer at orientation 15°, the *magenta* layer at orientation 75°, and the *yellow* layer at orientation 0° and (b) enlarged part of the halftone showing the new

colorants *red*, *green*, *blue* in regions where two of the *cyan*, *magenta*, and *yellow* ink dots overlap and *black* where the three ink dots overlap

Demichel Equations, Fig. 2 Example of a halftone with one *cyan* ink halftone dot (*dashed-dotted*) and one *magenta* ink halftone dot (*dashed*), yielding four different colorant surfaces, namely *white*, *cyan* only, *magenta* only, and *blue*

superposed with yellow), blue (cyan superposed with magenta), and black (cyan superposed with magenta and yellow). These colored dot portions are called “Neugebauer primaries” or simply “colorants.”

The *Demichel equations* enable calculating the relative surface covered by each colorant. They assume that the ink layers are printed independently one from another. In the present context, independence means that if a light ray hits a given position on the paper, the probabilities that the different halftone ink layers contain an ink dot at this position are independent one from another. As illustration, consider a first layer (cyan) whose halftone dot grows horizontally and a second ink layer (magenta) whose halftone dot grows vertically.

Let us assume that the total surface of the halftone element is one. The respective surface coverages of the cyan and magenta inks are respectively c and m , having values between 0 and 1. Let us assume that light rays are thrown into the halftone element surface, and that their probability to fall within a specific location of that surface follows a uniform distribution. Then the probability $P(c)$ to fall on a cyan ink dot of surface coverage c is equal to c and the probability $P(m)$ to fall on a magenta ink dot of surface coverage m is equal to m .

The halftone surface is a “puzzle” of juxtaposed colorants, formed by the paper, the inks, and their superpositions. In Fig. 2, the *colorant cyan* is the region covered by ink cyan only, without superposed magenta, and the *colorant magenta* is the region covered by ink magenta only, without superposed cyan. *Colorant white* is the region covered by no ink, and *colorant blue* is the region covered by both cyan and magenta inks.

If the ink halftone dots are laid out independently, as in Fig. 2, the probability of a light ray to hit the cyan colorant is the probability of hitting the cyan ink multiplied by the probability of not hitting the magenta ink. Similar considerations apply for the other colorants. We obtain

$$\begin{aligned}
 P(\text{Colorant} = \text{purecyan}) &= P(c) \cdot (1 - P(m)) \\
 P(\text{Colorant} = \text{puremagenta}) &= P(m) \cdot (1 - P(c)) \\
 P(\text{Colorant} = \text{blue}) &= P(c) \cdot P(m) \\
 P(\text{Colorant} = \text{white}) &= (1 - P(c)) \cdot (1 - P(m))
 \end{aligned} \tag{1}$$

Since for an incoming photon the probability to hit a given colorant is proportional to the surface coverage of that colorant, we can deduce the surface coverages of the individual colorants

$$\begin{aligned}
a_c &= P(\text{Colorant} = \text{purecyan}) = P(c) \cdot (1 - P(m)) = c \cdot (1 - m) \\
a_m &= P(\text{Colorant} = \text{puremagenta}) = P(m) \cdot (1 - P(c)) = (1 - c) \cdot m \\
a_b &= P(\text{Colorant} = \text{blue}) = P(c) \cdot P(m) = c \cdot m \\
a_w &= P(\text{Colorant} = \text{white}) = (1 - P(c)) \cdot (1 - P(m)) = (1 - c) \cdot (1 - m)
\end{aligned} \tag{2}$$

This calculation of colorant surfaces has been introduced by Demichel [3] and further elaborated by Neugebauer [4].

Along the same reasoning lines, with 3 inks, we obtain Eq. 3 expressing the 8 colorant surface coverages as a function of the cyan (c), magenta (m), and yellow (y) ink surface coverages. The

colorants are white, cyan, magenta, yellow, red (superposed magenta and yellow), green (superposed cyan and yellow), blue (superposed magenta and cyan), and black (superposed cyan, magenta, and yellow) with respective surface coverages a_w , a_c , a_m , a_y , a_r , a_g , a_b , and a_k .

$$\begin{aligned}
\text{white : } a_w &= (1 - c) (1 - m) (1 - y); & \text{cyan : } a_c &= c (1 - m) (1 - y) \\
\text{magenta : } a_m &= (1 - c) m (1 - y); & \text{yellow : } a_y &= (1 - c) (1 - m)y \\
\text{red : } a_r &= (1 - c) m y; & \text{green : } a_g &= c (1 - m)y \\
\text{blue : } a_b &= c m (1 - y); & \text{black : } a_k &= c m y
\end{aligned} \tag{3}$$

With 4 inks we obtain similar expressions (4) for the surface coverages of the 16 colorants, where k is the surface coverage of the black ink:

$$\begin{aligned}
\text{white : } a_w &= (1 - c) (1 - m) (1 - y) (1 - k); & \text{cyan : } a_c &= c (1 - m) (1 - y) (1 - k) \\
\text{magenta : } a_m &= (1 - c) m (1 - y) (1 - k); & \text{yellow : } a_y &= (1 - c) (1 - m)y (1 - k) \\
\text{red : } a_{my} &= (1 - c) m y (1 - k); & \text{green : } a_{cy} &= c (1 - m)y (1 - k) \\
\text{blue : } a_{cm} &= c m (1 - y) (1 - k); & \text{chromatic black : } a_{cmy} &= c m y (1 - k) \\
\text{black : } a_w &= (1 - c) (1 - m) (1 - y) k; & \text{cyanBlack : } a_{ck} &= c (1 - m) (1 - y) k \\
\text{magentaBlack : } a_{mk} &= (1 - c) m (1 - y)k; & \text{yellowBlack : } a_{yk} &= (1 - c) (1 - m)y k \\
\text{redBlack : } a_{myk} &= (1 - c) m y k; & \text{greenBlack : } a_{cyk} &= c (1 - m) y k \\
\text{blueBlack : } a_{cmk} &= c m (1 - y) k; & \text{totalBlack : } a_{cmyk} &= c m y k
\end{aligned} \tag{4}$$

These equations are valid in all cases where the ink halftone dots are laid out independently, e.g.,

in stochastic screening, in error diffusion, and in mutually rotated clustered dot or line screens [5].

Definition

Deuteranopia (from the Greek *deuteros*: second + *an*: not + *opia*: a visual condition) is a congenital form of severe color vision deficiency (dichromacy) affecting the red-green opponent color system. Deuteranopes do not distinguish between colors along a specific direction (deuteranopic confusion lines) in color space and are able to match all colors using two primaries (unlike trichromats who require three primaries). Deuteranopia is linked to the X-chromosome and arises from loss or alteration of the gene encoding the opsin of the middle-wavelength (M-) photopigment, this malstructure resulting in the absence of functioning M-cones in the retina. Deuteranopia follows a recessive pedigree pattern, with incidence of ca. 1% in the Caucasian male population. It is distinct from deuteranomaly in which some degree of discrimination among such colors remains.

Retinal Mosaic

At the level of retinal function, deuteranopia is the absence of M-cones (Fig. 1) (► [Cone Fundamentals](#)), i.e., cone cells expressing a photopigment containing an M-opsin component, tuned for selective sensitivity to medium- to longer-wavelength light such as green and yellow [1].

Genetic Background

Functional loss of the L-cone photoreceptor cells is caused by a mutant cone photopigment gene on the X-chromosome (► [Genetics of Photoreceptors, Genetics and Color Vision Deficiencies, Genes of Cone Photopigments, Genes and Cones](#)). The gene coding for the M-opsin may be missing altogether from a deuteranope's genome; it may be replaced by a second copy of the L-opsin (sensitive to longer wavelengths); or it may be present but damaged so that the protein is not expressed or cannot be transported to the ciliary segment of cone cells expressing that gene [1].

Deutanopia, Fig. 1 Adaptive optics retinal imaging: pseudocolor image of the deutanopic cone mosaic, all cones are of the L- (“red”) or S- (“blue”) type. (Source: Carroll et al. [1]; Fig. 4b, p. 8465. Copyright (2004) National Academy of Sciences, USA)

When present, one or more copies of the M-opsin gene are located on the X-chromosome, preceded by one copy of the L-opsin gene (► [Genetics of Photoreceptors, Genetics and Color Vision Deficiencies, Genes of Cone Photopigments, Genes and Cones](#)). This architecture, and the high similarity of the two genes, facilitates a recombination of DNA during meiotic crossover, leading to deleterious mutations of the M-opsin-encoding gene or its replacement by the L-opsin [2].

With two X-chromosomes, females are far less prone to deutanopia. Notably, mothers and daughters of deuteranopes can be heterozygous for deutanopia (i.e., carriers of the condition) with one normal and one aberrant X-chromosome; the former is active in a portion of their cone cells, with normal and abnormal areas interspersed across the retina. Despite having enough M-cones to sustain normal trichromatic vision, deutanopia carriers manifest subtle departures from it, with reduced subjective prominence of red-green dissimilarity [3, 4], more frequent Ishihara test errors, and wider anomaloscope matching ranges [5] (► [Color Vision Testing](#)).

Confusion Lines

L-signal/M-signal comparison in bipolar ganglion color-comparison cells is not present in deuteranopes (Color Vision, Opponent Theory); hence, there is no difference in appearance of any colors which differ only in the L–M signal. That is, although deuteranopes lack the M- or “green” cones, they are not “green-blind” in a literal sense but rather are red-green-blind. Examples of colors confused by deuteranopes are red, yellow, and green or cyan, gray, and purple. Plotted in a chromaticity diagram (► [CIE 1931 and 1964 Standard Colorimetric Observers: History, Data and Recent Assessments](#)), the confused colors lie on straight “confusion lines” that converge at the deutanope copunctal point [6] (Fig. 2).

Luminous Efficiency and Wavelength Discrimination

The absence of M-cones has little effect on deuteranopes’ sensitivity to colors. Their luminosity function has peak sensitivity around 560 nm, compared to the normal trichromatic peak near 555 nm, slightly redshifted toward the λ_{max} of the L-cone pigment [7, 8].

Hue discrimination, as a function of wavelength, is considerably worse for deuteranopes than for normal trichromats. Their lowest discrimination thresholds ($\Delta\lambda$), approaching the trichromatic value, are in the deutanopic “neutral point,” 495–500 nm (see below). $\Delta\lambda$ rises on both sides of this minimum, increasing rapidly on the short-wavelength side ($\lambda < 480$ nm) and on the long-wavelength side ($\lambda > 520$ nm) until wavelengths are not distinguished beyond approximately 530 nm [7].

Color Perception

A deutanope recognizes far fewer distinct colors than a trichromat (► [Color Categorization and Naming in Inherited Color Vision Deficiencies](#)). Deutanopic naming of spectral colors reveals a

Deuteranopia,

Fig. 2 Confusion lines indicate colors that cannot be distinguished by a deuteranope. The line going through the white point (W) indicates neutral (achromatic) colors. The lines converge at the copunctal point defining the chromaticity of the missing M-cone fundamental. Drawn in the CIE 1931 chromaticity diagram [6]

“neutral zone” of subjective gray ranging between 495 and 505 nm, with midpoint at ca. 498 nm [9]. For a deuteranope, all equiluminant colors, instead of being arranged in a two-dimensional plane (► [Psychological Color Space and Color Terms](#)), form a single-dimensional line, running between the two extremes of saturated blue and saturated yellow [10]. Deuteranopes distinguish approximately 31 steps along this line, each corresponding to a separate band of interchangeable colors [8]. The usually separate chromatic qualities of “saturation” and “hue” are thus combined along this line. This deuteranopic linear representation of equiluminant colors is part of a broader reduction of a three-dimensional into a two-dimensional color space.

Whether the subjective qualities of the two extremes are identical to the normal trichromatic “blue” and “yellow” remains controversial and rests on reports from a handful of individuals with unilateral dichromacy. The blue-yellow convention is used in dichromacy simulation software, which converts color scenes to show how a deuteranope would see these [11].

Despite this model of a two-hue palette for self-luminous colors, the color percepts of deuteranopes remain in question [12]. Their object-color palette was proved to include all six Hering component colors (red, green, blue, yellow, white, and

black) [13]. However, in contrast to normal trichromats, deuteranopes perceive only a weak green component in object colors and do not experience “unique green”; their red and green components are confounded with an achromatic element (► [Color Categorization and Naming in Inherited Color Vision Deficiencies](#)).

Diagnosis of Deuteranopia

Deuteranopia can be diagnosed using several tests varying in sensitivity, selectivity, and ease of use [14] (► [Color Vision Testing](#)). Pseudoisochromatic plates and arrangement/panel tests directly address a deuteranope’s confusions between color pairs along the confusion axis. Both types of tests have the advantage of rapid administration and ease of interpretation, making them suitable for field studies or epidemiological applications.

In the pseudoisochromatic tests, Ishihara plates and Hardy-Rand-Rittler test (► [Pseudoisochromatic Plates](#)), each diagnostic plate shows a normal observer design (digit or curved lines) defined by a color difference which disappears for deuteranopes, so that the design vanishes or is supplanted by an alternative design, demarcated by a different chromatic distinction.

In the arrangement tests (Farnsworth-Munsell 100 hue test, Farnsworth D-15 test), the one-dimensionality of deuteranope's color "plane" collapses a color circle into a line (► [Color Circle](#)), causing drastic departures from a normal observer's sequence. Errors, or cap transposition "distances," are summed to quantify the severity of deuteranopia. Plotted graphically, the transpositions in the D-15 manifest as diametrical circle crossings, indicating the deuteranopic angle of the confusion axis (► [Color Perception and Environmentally Based Impairments](#)).

The "gold standard" of diagnosis of deuteranopia is the Rayleigh match on a small viewing field (2°) of the Nagel anomaloscope. Conventionally, the levels of 670 nm (red) and 545 nm (yellow) lights are fixed, so that either wavelength at maximum setting stimulates L-cones equally: the so-called deutan mode in which a deuteranope will match *any* red-green ratio to the yellow light by adjusting the luminance [14] (S-cones being unresponsive in this spectral range). Notably, unlike protanopes (► [Protanopia](#)), deuteranopes do not dim the yellow light when adjusting it to the mixed light that is mainly red – the estimate that is diagnostic or differentiating the two red-green deficiency types. Similar to protanopes, when tested with a large viewing field (10°), in setting Rayleigh matches, the majority of deuteranopes perform as anomalous trichromats. Various factors related to retinal eccentricity are presumed, e.g., rod intrusion, S-cone intrusion, spatial variation in the macular pigment, etc. [8].

More recently developed computerized tests for color vision diagnosis, the Cambridge Colour Test and Colour Assessment and Diagnosis test (► [Color Vision Testing](#)), interactively quantify any loss of chromatic sensitivity along the deuteranopic confusion line. For a deuteranope, in the frame of the CIE (u' , v') 1976 chromaticity diagram (► [CIE \$u'\$, \$v'\$ Uniform Chromaticity Scale Diagram and CIELUV Color Space](#)), a MacAdam ellipse of indistinguishable colors displays a major axis lengthened to infinity and orientation pointing to the deuteranope copunctal point [15, 16].

Incidence of Deuteranopia

Prevalence of inherited deuteranopia varies between human populations [17]. For Caucasian populations, the reported incidence of deuteranopia is 1.27% in males and 0.001% in females [8]. Recent surveys of red-green deficiency in populations of different racial origins found the incidence of deuteranopia in Caucasian males to vary between 0.96% and 1.37%. As is the case of protanopia (► [Protanopia](#)), in indigenous native American, Pacific, Asian, and African populations, the incidence of deuteranopia is markedly lower than in Caucasians, about half this rate, and, too, is observed to rise in coastal areas where migrant Europeans settled in historical times [17]. The increasing prevalence of congenital red-green deficiencies, including deuteranopia, has tentatively been explained by a relaxation in selection pressures as hunting and gathering cultures evolve toward industrialized societies [8]. More recently, however, it is rather attributed to genetic drift and founder events (variable sampling of the gene pool contingent on the population size) [17].

Diffuse Lighting

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Definition

Lighting in which the light on a point, plane, or object in the lit space is incident with equal luminous intensities from all directions.

Daylighting

The sun, of course, is the primary source of daylight. When there are clouds in the sky, part of the

primary sunlight is absorbed and part reflected from the clouds. The result is a combination of direct sunlight and secondary reflected light from the clouds. In a situation where the sky is completely covered with clouds, the overcast sky acts as a perfect diffuser, resulting in complete diffuse daylighting. The overcast sky lighting condition is used by architects and lighting designers to calculate the lowest level of daylight contribution in buildings. With a partly overcast or complete clear sky, the contribution will be higher. To standardize these calculations, CIE has introduced the so-called CIE overcast sky with a defined luminance distribution. The luminance of the CIE overcast sky is the highest in the zenith, the point straight above the point under consideration, and decreases to one third at the horizon. For simple noncomputerized calculations, sometimes the CIE uniform sky is used in which the luminance distribution of the sky is uniform.

Electric Lighting

Near complete diffuse electric lighting is obtained from indirect lighting in interiors. Here the electric lighting is directed toward the ceiling to create a near uniform ceiling luminance. The light reaches the working plane only after reflection from the ceiling. Since a white ceiling does usually not have a reflectance higher than some 70%, at least 30% of the light is absorbed at the ceiling.

In some interiors, artificial skies are created with luminous ceilings existing of large-sized luminaires with opal type of louvers. The lighting of these artificial skies is usually diffuse although, with LED or OLED solutions, nonuniform skies and consequently non-diffuse lighting can be created.

Conventional indoor lighting luminaires for general lighting purposes, in fact, have a diffuse component with, under elevation angles of some 60–70°, a directional component. Dependent on the actual light distribution of the luminaire, the lighting is more diffuse or more directional.

Consequences of Diffuse Lighting

The consequences of complete diffuse lighting are best explained by considering the condition of a clouded sky. The diffuse lighting of it is not appreciated very much: it gives a dull, monotonous impression in which shadows, depth, shape, and texture are poor or completely absent. This has negative consequences for both visual pleasantness and visual performance. An illustration of the latter is an entirely cloudy sky on a ski slope: irregularities and bumps in the snow cannot be seen because of the absence of shadows. Indeed it is generally considered dangerous to make a somewhat difficult descend under these viewing conditions.

Diffuse electric lighting has the same negative consequences for both pleasantness and visual performance. The effect of lack of shadows, here, is often referred to as bad modelling.

Good interior lighting consists of both a diffuse and directional component. This again is analogue to a relatively clear sky outdoors with a strong directional component from the sun with some diffuse light from a couple of white clouds.

Definition

The term *dye* refers to compounds which can impart color to a substrate when applied in solution from either aqueous or organic solvents. The substrates include textiles, plastics, polymers, etc. Both the applications to materials and color constitutions of dyes involve essentially chemical principles. Dyes and pigments are both commonly

applied as a coloring material, but they are distinguished on the basis of their solubility either in water or organic solvents; therefore dyes are soluble, whereas pigments are insoluble.

History of the Development of Synthetic Dyes

Until the middle of the nineteenth century, the dyeing of textiles and leather was carried out using dyes derived from animal and vegetable sources. Of such natural dyes, indigo is perhaps the most well-known and most important material [1]. Alizarin is the most important species of anthraquinone-based red dyes obtained from the roots of plants of the *Rubiaceae*. A highly prized plant was madder which produced dyeings on cotton known as Turkey Red by means of Ca-Al mordant. Also of importance in early times was the use of the red dye, Kermes, obtained from insects [1, 2]. In 1856, WH Perkin synthesized a brilliant violet dye, Aniline Purple (which later became known as Mauveine), by the oxidation of a mixture of aniline bases [3–5]. Perkin's (accidental) discovery of Mauveine and his development of methods to apply the dye to silk and cotton stimulated enormous commercial interest in dye synthesis. Further discoveries quickly followed, such as that of the diazo reaction by Griess in 1859 and the introduction of the first azo dye, Bismarck Brown, by Martius in 1863 [6] and the structural elucidation and synthesis of Alizarin that occurred in 1868 and Indigo by von Baeyer in 1883 and Heumann in 1890; shortly afterwards the first anthraquinoid vat dye indanthrone was prepared by Bohn in 1901 [6, 7]. As a result of intensive attempts to devise new dyes for application to the fiber cellulose acetate, the water-soluble *Ionamin* range of dyes was introduced in 1922 [8] which were the precursors of the current wide range of sparingly soluble disperse dyes. The first reactive dyes for cotton were introduced by ICI in 1956; such dyes are able to attach covalently to cellulosic fiber, thereby offering dyeings of excellent fastness to washing and wet treatments [9]. From the 1990s, non-textile applications for dyes, such as

information technology, reprographics, optoelectronics, and solar cells, have contributed to the diversity of modern synthetic dyes [1, 10].

Principles of Color Constitution in Dyes

When ultraviolet or visible radiation is absorbed, an n or π electron is promoted and occupies an empty π^* or σ^* antibonding orbital, the wavelength, λ , of the photon being equal to the energy difference, ΔE , between the two levels, ground state and excited state, involved:

$$\lambda = hc/\Delta E$$

where h is Planck's constant and c the velocity of light.

When the energy difference is equal to the energy of visible light, the compound has an absorption band in the visible region (400–700 nm) and exhibits the color complementary to that of the absorbed light [7].

Early Theories Using Qualitative Method

The elucidation of the relationship between the color of dyes and their chemical constitution has attracted much attention. In 1876, Witt suggested that color arises from the combination of unsaturated groups, such as $-\text{N}=\text{N}-$, $-\text{C}=\text{O}$, and NO_2 , with basic groups, such as $-\text{NH}_2$, $-\text{OH}$, and $-\text{NR}_2$, within a dye molecule. Witt defined the former groups as *chromophores* and the latter as *auxochromes*. The terminology of *bathochrome* and *hypsochrome* was also coined at the same time [6, 11]. Hewitt defined the role of conjugation in a dye molecule as “the longer the conjugated chain, the more bathochromic the dye” and pointed out the importance of a conjugated chain for the production of color. With the discovery of the electron in 1897 [12], attention was then given to the behavior of electrons within dye structures as providing the origin of color.

Modern Theories

All modern theories involve two distinct approaches, namely, the Valence Bond (VB) and Molecular Orbital (MO) theories, which are developments from quantum mechanics. VB

theory is principally based on bonding valence electron pairs localized between specific atoms in a dye molecule [12], whereas MO theory has played a key role in the development of modern color theories for solving the intricate relationships between color and chemical constitution. A satisfactory method to calculate the transition energy and intensity of visual color was developed in terms of the Linear Combination of Atomic Orbitals (LCAO) method and the Hückel Molecular Orbital (HMO) method, which were originally developed for unsaturated hydrocarbons. Hückel assumed that the transition state would correspond to the energy difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO).

Classification and Nature of the Chromogens

Colored organic molecules can be rationalized by classification into four groups [13]:

1. $n \rightarrow \pi^*$ chromogens
2. Donor–acceptor chromogens
3. Acyclic and cyclic chromogens
4. Cyanine-type chromogens

Thus, dyes which exhibit electronic transitions from a lone pair, nonbonding atomic orbital of the molecule belong to the $n \rightarrow \pi^*$ group of chromogens. However, most dyes are regarded as donor–acceptor chromogens, which, characteristically, possess electron donor and electron acceptor groups that are linked by a conjugated π -electron system (the conjugating bridge). Depending on the role of the accepting group, donor–acceptor chromogens can be subdivided into simple acceptors or complex acceptors, as represented in Fig. 1 [13].

For azo dyes, in general, the strength of the electron acceptor correlates closely with the Hammett σ constant of the substituent. As the value of the σ constant of a substituent increases, the electron acceptor group exerts a more powerful effect and produces a larger bathochromic shift (absorption maximum moves to longer wavelength).

Effect of Substituents on Color in Azo Dyes

In simple azo dyes, a weak long-wavelength absorption is observed due to the overlap of the

Dye, Fig. 1 Schematic representation of simple acceptor and complex acceptor

D

atomic orbitals of the two nitrogen atoms, giving rise to an $n \rightarrow \pi^*$ transition. The intensities of $n \rightarrow \pi^*$ transitions vary depending on whether the transition is symmetrically allowed or forbidden [14]. A weak absorption band, involving $n \rightarrow \pi^*$ transition, tends to be overshadowed by the more intense $\pi \rightarrow \pi^*$ absorption band. If an electron-donating group, such as an dialkylamino group, is introduced into the cyclic unsaturated residue (**D**) of an azo dye, of general formula $A - N = N - D$, an intense new absorption band arises as a result of a $\pi \rightarrow \pi^*$ transition, which is referred to as a charge-transfer (CT) transition. The migration of a π electron delocalized in the nitrogen orbital of the amino group towards the azo dye is responsible for such charge-transfer transitions [13]. A further bathochromic shift can be exerted by the additional incorporation of electron-withdrawing groups, such as NO_2 , CN, and halogen, into the **A** ring. The greatest effect in terms of longer wavelength is achieved by placing the substituents at positions *ortho*- or *para*- to the azo group, which maximizes conjugation. Similarly, electron-donating groups situated *ortho* to the azo linkage in the **D** ring normally give rise to the most effective bathochromic shifts [13, 15].

Principles of Photofading in the Dye Molecule

Jablonski Diagram

Theoretically, once a dye molecule absorbs a photon from incident light, an electron will be excited to different energy levels. As depicted in Fig. 2,

the excited molecule tends to lose its energy and returns to the ground state, this process involving the emission of fluorescence or phosphorescence, or can undergo a chemical reaction, leading to decomposition. This type of reaction is referred to as a *photochemical reaction* or photofading. Not surprisingly, both the first singlet excited state and the first triplet excited state are the crucial energy levels for this reaction. The longer lifetime of the triplet excited state may be linked with a higher likelihood of photodegradation of the dye molecule [6, 13].

Internal conversion of the excited state is expected to be the fastest step for dyes and UV stabilizers that are employed in polymers, whereas fluorescence should be both dominant and fastest for optical brightening agents and laser dyes. Intersystem crossing should be fastest for dyes used as sensitizers [6].

Types of Photoreaction

Photofading may occur in different ways depending on the nature of the substrates, wavelength distribution of the incident light, the presence of moisture, and air and dye structure. In general, two principal types of photochemical reaction are recognized: photooxidation and photoreduction. The influence of substituents on degradation rate has been rationalized by plotting photofading rate against Hammett σ constant for aromatic azo dyes containing various substituents. Thus, if the fading rate increases as electron-withdrawing power increases (higher σ value), a reductive mechanism is favored (positive), whereas a decreased fading rate is observed when oxidative degradation dominates

Dye, Fig. 2 Energy-level scheme of a photoexcited dye molecule (Jablonski diagram)

(negative) [11, 16]. As far as photooxidation is concerned, singlet oxygen plays a very important role.

Solvatochromism of Dyes

Solvatochromism can best be described as the effect of a solvent on the color of a dye. Solvent–solute interactions have various influences on the absorption spectrum, such as λ_{max} value and the intensity of a band; the bandwidth may also vary.

Solvatochromism Types

Generally, in many dye molecules, the ground state is less polar than the excited state so that a polar solvent will tend to stabilize the excited state more than the ground state, leading to a bathochromic shift in the absorption maximum; this effect is termed positive solvatochromism. In contrast to positive solvatochromism, negative solvatochromism is relatively rare and is most often observed in dyes that contain a delocalized charge [6]. The interaction of a solvent with a dye molecule is greatest in polar solvents, for example, ethanol, which possess a strong permanent dipole, and is most pronounced with a solute molecule which contains a permanent dipole. Intermolecular hydrogen bonding can also give rise to shifts in the absorption spectrum,

particularly in case of $n \rightarrow \pi^*$ bands. For heteroatoms, such as nitrogen, sulfur, and oxygen, the nonbonding lone pair electrons can form intermolecular hydrogen bonds with suitable protic polar solvents, such as ethanol or water. Accordingly, the excitation energy will be raised by the hydrogen bond, which stabilizes the n -electrons resulting in a hypsochromic shift in the absorption spectrum [13, 17].

Halochromism of Dyes

This term is defined as the color change of a substance accompanying a change in the pH of the solution [13]. Although many types of aminoazo dyes show this effect, it is observed only when the amino group is situated *para* to the azo linkage.

Halochromism Types

In contrast to hydroxy azo dyes, in acidic solution, many dyes derived from 4-aminoazobenzene are susceptible to protonation either at the β -nitrogen atom of the azo linkage, to give the azonium cation, or at the amino nitrogen atom to produce an ammonium ion. Bathochromic shifts combined with increased color intensity are often observed for the azonium ion. This shift is termed as a positive halochromism, whereas the opposite

Definition

Dye-sensitized solar cells (DSSCs) are thin-film photovoltaic devices that use dyes covalently bonded to a semiconductor surface to harvest energy (photons) from the sun and convert it into electrical energy. In DSSC fabrication, a dye-containing thin semiconductor film, typically titanium dioxide, is applied to a conductive glass substrate. The resulting photoanode is attached to a counter electrode, typically a platinum-coated conductive glass. A liquid electrolyte is injected between the two electrodes to complete the circuit and ensure dye regeneration. The dyes used, also known as photosensitizers, are often ruthenium-complexed compounds owing to their exceptional photophysical and photochemical properties and long lived excited states, but other classes used include metal-free dyes and various other high efficiency metal-complexes such as Zn-porphyrins (A3B type). Molecular engineering of photosensitizers for DSSCs has been a significant research focus in the last three decades, as the photosensitizer is responsible for the quantity and energy of harvested photons.

Introduction

Dye-sensitized solar cells (DSSCs) emerged from a research effort aimed at finding alternatives to silicon solar cells, which require high fabrication temperatures. While DSSCs do not perform as efficiently as their silicon counterparts under direct lighting conditions, they perform just as

well or better under all other conditions – in particular under diffuse light [1]. Additionally, they are less expensive and easier to fabricate than silicon solar panels, making the cost per Watt advantageous. Because DSSCs do not require high temperatures to fabricate, they can be made on flexible substrates such as plastics to furnish devices that are flexible and can be also integrated into fabrics [1, 2].

Structure of Dye-Sensitized Solar Cells

The structure of a dye-sensitized solar cell is shown in Fig. 1. The DSSC is constructed by sandwiching an electrolyte between a photoanode and a counter-electrode. Both electrodes are fabricated on conductive glass, which is coated with fluorine-doped tin oxide (FTO) to make it conductive.

Photoanode

The photoanode comprises a metal oxide, typically nanocrystalline TiO_2 , with an adsorbed dye for harvesting solar energy. The excited state of the dye should be at a slightly higher energy level than that of the conduction band edge of the TiO_2 for thermodynamically favorable electron injection from the first excited state singlet and/or triplet of the dye into the conduction band edge of semiconductor.

For fabrication of the photoanode, a conductive FTO-glass is printed with porous TiO_2 . For optimized DSSC efficiency, TiO_2 is deposited in

multiple layers, the first of which is called the blocking layer because it minimizes electron transfer between the electrolyte and the conductive FTO on the glass surface [1]. Once the $\sim 50\text{ nm}$ thick blocking layer of TiO_2 nanoparticles has been annealed, one or two mesoporous layers are printed on top. This typically consists of a $\sim 10\text{ }\mu\text{m}$ thick light absorption layer with particle size $\sim 20\text{ nm}$ and a $\sim 3\text{ }\mu\text{m}$ light scattering layer with particle size $\sim 400\text{ nm}$. These two layers allow large surface areas for increased dye adsorption and the pores allow electrolyte diffusion. Finally, a $\sim 1\text{ nm}$ thick pure TiO_2 shell is deposited via aqueous TiCl_4 dipping. This covers any impurities that may be on the mesoporous surface and increases surface roughness (and therefore dye adsorption), lowering the Fermi level, and hence the energy level of the conduction band edge of TiO_2 . The lower (more negative) free energy of the conduction band increases the driving force of electron injection from the excited state of the dye and leads to longer electron lifetimes [1].

Counter Electrode

The counter electrode functions as the cathode of the DSSC and is responsible for reducing I_3^- to I^- at the interface. The counter electrode can be fabricated by printing a layer of catalytic platinum paste on FTO-glass and annealing. These pastes are typically comprised of platinum chloride compounds which thermally decompose to produce Pt nanoclusters [1]. In addition to the cost and energy

Dye, DSSC, Fig. 1

Architecture of a standard dye-sensitized solar cell illustrating light absorption, dye excitation, electrodes, electron injection from the dye into TiO_2 , and role of electrolyte

benefits of using transparent catalytic Pt films, there are also stability benefits, as electro-deposited or vapor-deposited Pt films tend to dissolve in I^-/I_3^- [1]. As an added advantage, the DSSC can be illuminated from either side, increasing the incident light in applications such as windows. Furthermore, the thickness of the active TiO_2 layer is responsible for the cell transparency, which creates a tradeoff between the cell's efficiency and transparency.

Electrolyte

The most common electrolyte system used in DSSCs is an I^-/I_3^- redox couple in an organic solvent. The electrolyte system is responsible for accepting incoming electrons from the platinum counter electrode and for regenerating the dye via reduction. For unsealed devices, the electrolyte is allowed to diffuse between the two layers of glass that make up the “sandwiched” DSSC construction. For sealed devices, a hole is drilled in the counter electrode before the photoanode and counter electrode are sealed together in the sandwich construction using an ionomeric film. The electrolyte solution is then injected into the cavity between the two active layers via the hole in the counter electrode [3].

While the electrolyte is intended to play the beneficial role of dye regeneration, it can also have detrimental effects. Both the I^-/I_3^- and the organic solvent components are volatile, and as they evaporate the effectiveness of the device is diminished until the solution is replenished [4]. Especially problematic in copper-complexed dyes is the potential for a coordinating solvent to bind to the copper center and prevent dye regeneration, resulting in poor stability and efficiency [4]. Additionally, I^-/I_3^- itself absorbs light and can compete with the dye for light absorption. For these reasons, the search for alternatives to this electrolyte system has been a significant area of research [4, 5]. Recently, researchers have investigated cobalt- and copper-based systems. In every case, it is important to choose an electrolyte that is compatible with the chosen dye. For example, a copper-complexed dye and a copper-based electrolyte would not be compatible if ligand exchange occurs, resulting in the

degradation of both the photosensitizer and the electrolyte. The I^-/I_3^- electrolyte system has been optimized for use with ruthenium-complexed dyes in DSSCs.

Photosensitizer

The photosensitizer is responsible for light absorption and the resultant generation of excited electrons. When the TiO_2 layer is completed, the TiO_2 -coated glass is soaked in a dye solution for 20–24 h at approximately 25 °C. This dye solution sometimes contains a co-adsorbent to prevent dye aggregation, which can inhibit electron injection. The photoanode is then removed from the dye solution, rinsed, and dried. The dipping process can be more complicated for certain copper-complexed dyes, as the dyes themselves are assembled in-situ and require a three-step dipping process [6]. The photosensitizer is the component of the cell that absorbs light, which excites electrons to an excited state in the process. The mechanism by which the excited dye relaxes to the ground state is of great importance for DSSCs, because many of the available relaxation mechanisms preclude injection of electrons into the metal oxide. Examples of dyes that have been developed for commercial DSSC devices are shown in Fig. 2. These dyes have a photon to current conversion efficiency (η) of 10% (N3), 11.18% (N719), 9.1% (TA-St-CA) [7, 8].

Ru (II) complexes exhibit strong spin-orbit coupling [9], and their resulting long-lived excited states have proven advantageous for photocurrent generation in DSSCs [9–13]. Since the first report of an Ru-based DSSC by Michael Grätzel in 1991 [13], a significant research effort has focused on structural modifications to Ru(II) polypyridyl complexes for optimized function in DSSCs [14, 15]. In addition, several other broad classes of dyes have emerged in recent years. Organic (metal-free) dyes have been a popular focus, with the benefit of eliminating the need for rare and expensive Ru while achieving high molar extinction coefficients and conversion efficiencies [1, 16]. Porphyrin dyes recently made a dramatic entrance to the field with 11% efficiency in 2010 [17] and have since reached 13% [18]. There has also been some work on ruthenium-free metal-

Dye, DSSC, Fig. 2

Examples of
photosensitizers used in
commercial DSSCs

based dyes, including those based on osmium, copper, iron, platinum, and rhenium [1].

There are several basic structural requirements of dyes for metal-based DSSCs. The first and most important are anchoring groups for TiO₂ adsorption and electron injection. In Ru(II) complexes for DSSCs, these are typically acidic functional groups such as carboxylic or phosphonic acid groups, but can include sulfonic acid, cyanoacrylic acid, and others [19]. Some devices have been reported with no such anchoring groups, but they exhibit very poor electron injection and stability [20]. While not strictly required for a metal-based sensitizer, strong electron-donating substituents are nearly ubiquitously employed on ancillary ligands to broaden light absorption via destabilization of the HOMO [21].

Working Function and Principles

A dye-sensitized solar cell operates as shown in Fig. 3. First, incident light excites an electron within the photosensitizer (step 1 in Fig. 3). If the thermodynamic driving force ($-\Delta G$) is sufficient, the electron is injected from the excited state of the dye into the conduction band edge of the TiO₂ layer (step 2). If the electron successfully avoids recombination (step 5), it moves into the external circuit. Once the electron reaches the platinum counter electrode, it then enters the cell via reduction of the I^-/I_3^- couple at the Pt/electrolyte interface (step 4). The electrolyte subsequently regenerates the original dye via reduction (step 3), and the cycle

is complete [15]. The red arrows in Fig. 3 represent processes that decrease the efficiency of the DSSC. Step 5 represents an electron that is injected into the conduction band of TiO₂ but subsequently recombines with the dye to regenerate the ground state. Step 6 represents reduction of the redox mediator by electrons in the conduction band of TiO₂ [14].

Thermodynamic considerations are critical when selecting the components of a DSSC. The excited state oxidation potential (ESOP) of the dye must be at least 150–200 mV greater than the conduction band of the metal oxide for favorable electron injection. Additionally, the HOMO of the dye must be at least 200–300 mV lower than that of the redox potential of the electrolyte for favorable dye regeneration via reduction [14, 22].

Photovoltaic Parameters

The most commonly cited photovoltaic parameter is the power conversion efficiency (PCE or η). It is defined as the maximum output power as a percent of the input power, as shown in Eq. 1 [1, 23]:

$$\eta = \frac{P_{\max}}{P_{\text{in}}} \times 100\% \quad (1)$$

The power conversion efficiency is obtained from current density-voltage measurements. The cell is irradiated with a one Sun solar simulator and current density is measured at each applied voltage, generating current density-voltage curves such as that shown in Fig. 4 [23].

Dye, DSSC, Fig. 3

Working principle of DSSCs

Dye, DSSC, Fig. 4 Illuminated current density-voltage curve of an ideal solar cell

J_{sc} is the short circuit photocurrent density, where $V = 0$ and each excited electron is injected virtually instantaneously after generation. V_{oc} is the open circuit photovoltage, where $J = 0$ and every excited electron recombines rather than generating current. At some intermediate point along the $J - V$ curve is the maximum power point (mpp), where $J = J_{mpp}$, $V = V_{mpp}$, and $P = P_{max}$. As we can see from Fig. 4:

$$P_{max} = J_{mpp} V_{mpp} \quad (2)$$

$$\frac{P_{max}}{J_{sc} V_{oc}} = \frac{J_{mpp} V_{mpp}}{J_{sc} V_{oc}} = FF \quad (3)$$

The ratio in Eq. 3 is defined as the fill factor (FF), and allow us to express the efficiency in terms of J_{sc} and V_{oc} :

$$\eta = \frac{J_{sc} V_{oc} FF}{P_{in}} \quad (4)$$

The fill factor represents the fraction of maximum theoretical power the solar cell can achieve, and reflects the overall quality of the device.

Final Considerations

A significant portion of DSSC research has involved the design of new sensitizers, with the goal of broadening solar energy harvesting, improving electron injection dynamics, increasing excited state lifetimes, and improving stability, all with the goal of increasing long-term efficiency of DSSCs. Four main classes of dyes suitable for DSSCs have emerged: metal-based coordinate complexes (mostly ruthenium-based), organic dyes (metal-free), Zn-porphyrin dyes, and natural dyes.

Design Features of Photosensitizers

Dyes for DSSCs must be structurally suited to the application by satisfying the following requirements: (1) the dye must exhibit affinity for the metal oxide, which is accomplished through the incorporation of anchoring groups; (2) the HOMO (GSOP) and ESOP must align with the conduction band edge of TiO_2 and the redox potential of I^-/I_3^- , respectively, for thermodynamically favorable electron injection and dye regeneration;

(3) the LUMO should be centered on the anchoring ligand for kinetically favorable electron injection into the semiconductor; (4) the dye must be not only photostable, it must also be chemically stable over at least 10^8 oxidation-reduction cycles. This corresponds to an approximated 20 years of continuous irradiation [14].

Different dye classes employ different structural features to achieve these goals. Strong electron donors such as carbazole and triphenylamine units are prevalent, especially in organic dyes and transition metal coordinate complexes [1, 17]. Donor-free thiophene derivatives have also become popular substituents because they function as hole-transporting domains and increase conductivity within the device [14].

Ruthenium complexes are by far the most popular photosensitizers for a variety of applications, and DSSCs are no exception. Ruthenium polypyridyl complexes have high molar absorptivities, strong MLCT absorption bands in the visible range, and long excited state lifetimes due to an easily accessible triplet state, making them the long-standing prototype [15].

Dye, Functional

Sung-Hoon Kim and Eun-Mi Lee
Department of Textile System Engineering,
Kyungpook National University, Daegu,
Republic of Korea

Definition

Since the introduction of the first commercially available synthetic dye, *mauveine*, in 1856, traditional organic dyes have been used for the coloration of textiles by means of dyeing technology. The term “functional dye” was first coined by Japanese scholars in 1981 and stemmed from interest and activity in the field of dye chemistry interrelated with high-technology applications [1–6]. Nowadays, the term *functional dyes* refers to ultraviolet (UV) and particularly infrared (IR) active molecules which have been specifically designed for high-technology applications in fields such as electronic materials, electronic devices, reprographics, etc., as such “functional dyes” differ to traditional dyes.

Interactions of Functional Dyes

It is pertinent to examine the interactions of functional dyes with various agents before discussing the many and varied applications of functional dyes. Such interactions enable particular

phenomena to be associated with each application. Functional dyes are designed to interact with electromagnetic radiation, pH, electricity, heat, pressure, and even frictional forces.

Electromagnetic Radiation

Functional dyes interact with electromagnetic radiation in the near-UV (300–400 nm), visible (400–700 nm), and near-IR (700–1500 nm) regions to produce a variety of effects required for high-technology (hi-tech) applications. Selective absorption of nonvisible radiation, such as UV and particularly IR, is also important in applications such as optical data storage, computer to plate, security, and printing. A color change imparted by electromagnetic radiation is called *photochromism*. Photochromism is a chemical process in which a compound undergoes a reversible change between two states having separate absorption spectra, i.e., different colors. Although photochromism is undesirable in traditional textile dyes, it is widely used in, for example, spectacles and optical data storage. Indicator dyes are probably the most familiar example of a color-change effect.

Luminescence occurs when a molecule in an excited state, normally achieved by absorption of a photon, loses some or all of the excess energy as light rather than via the normal relaxation mode of heat loss. Luminescence from the first excited singlet state to the ground singlet state is known as *fluorescence*. Fluorescence is important in biological application, laser dyes, emissive displays, and in providing vivid, bright dyes, particularly for ink-jet printing.

Heat

Most molecules lose energy from the excited state as heat. The most efficient molecules for converting electromagnetic radiation into heat are those that absorb in the near-infrared region, namely, infrared absorbers (IRAs). IRAs have attracted much interest because of their use in laser thermal transfer, optical data storage, computer-to-plate printing, and as solar screens for car windscreens and windows.

Thermochromic dyes change color with temperature (heat). Thermochromic dyes find use in

Dye, Functional, Table 1 Application areas of functional dyes

Fields	Applications	
Data storage	Optical data storage	CD-R, DVD
	Printing	Ink for ink-jet printer, OPC, toner, thermal recording paper, D2T2
	Others	Pressure-sensitive paper, color shifting ink for counterfeit deterrence
Data display	Display	Color filter for LCD, organic EL, near-infrared absorption dyes for PDP
	Others	Digital papers, thermosensitive materials
Energy transfer	Solar cells	DSSC
	Others	Dye laser, nonlinear optical materials, organic semiconductor
Biomedical application		Diagnostic medical devices, laser dyes for photodynamic therapy

direct thermal printing and as temperature sensors, as well as in clothing and novelties.

Electricity

Functional dyes have been designed to interact with electricity to produce a color change or to fluoresce. *Electrochromic dyes* change their color, generally from colorless to colored, when an electrical voltage is applied. The main application areas for electrochromic systems are electrically switchable anti-dazzle rearview mirrors, glazing units for temperature and light control, as well as visual displays.

Frictional Force/Pressure

Piezochromic and *tribochromic functional dyes* have been designed to produce an electrostatic charge when mechanical means is applied, the former under applied frictional or grinding forces and the latter by pressure. Such compounds have not as yet enjoyed much commercial exploitation. Known as charge-control agents, *tribochromic* dyes are used in the toners for photocopiers and laser printers to both produce and regulate the triboelectric charge on the toner particles. Pressure-sensitive barochromic dyes find use in imaging (carbonless paper) and for testing pressure points in, for example, airplanes and cars.

Functional Dyes Classified by Application

As mentioned above, development of electronics industry and the affected industries is needed of

functional dyes, which are developed, discolored, or achromatized by very small energy such as light, heat, electricity, and so on. Functional dyes can be classified in several ways. This entry will describe specific examples of functional dyes by classified application such as data storage, data display, energy transfer, and so on. A list of fields and application of functional dyes are given in Table 1.

Data Storage

The data storage field can be divided into two main parts, namely, *optical data storage* and *printing*. The technologies related to printing seek to produce visible images on a hard copy, usually paper or special media; ink-jet, laser printing, photocopying, and thermal printing are examples of the printing techniques employed. However, there are other technologies which produce invisible images, usually for the entertainment and publishing fields, using functional dyes; *optical data storage* is such a technology which concerns invisible imaging.

In its broadest sense, optical data storage involves a medium which, by optical means, employs near-infrared radiation or visible light for the recording and retrieval of digital data. Various types of storage media have been developed, such as read-only compact discs (CD-ROM) to rewritable digital versatile discs (DVD-RW); optical data recording systems which use laser addressable organic dyes include WORM (write once read many), CD-R, and DVD-R.

The mechanism of optical recording using dyes involves converting excitation energy, which is generated by a focused laser beam, into thermal energy by non-radiative decay. In simple terms, a dye is coated onto a disc substrate to provide the recording layer. In writing mode, the laser is used near to full power and “blasts” holes in the very thin layer of dye at appropriate parts of the disc, as dictated by the digitally encoded information. When the information is retrieved, the power of the laser is turned down to avoid damaging the recording layer and is played over the surface of the disc to read the encoded signal with the aid of a detector. Since the mechanism of hole formation relies upon the dye absorbing laser radiation, heating up, and migrating from the hot region during the hole formation stage, the dye must absorb at the wavelength of the laser used. A number of technical criteria are demanded of suitable dyes, in addition to the general commercial requirements of low cost and high availability:

- Good solubility in the organic solvent used for spin coating the discs and the ability to form solid films.
- High stability for environmental and processing conditions, i.e., oxidation, hydrolysis, and light.
- High reflectivity of the solid film at the recording wavelength.
- Low thermal conductivity and hence high sensitivity for heat-mode recording.

The requirements for dyes in WORM, CD-R, and DVD-R media are very similar, but there are differences in their absorbance wavelength. Several types of infrared absorbers have received attention for use in optical data storage. Both phthalocyanine and cyanine colorants satisfy the commercially required technical criteria for optical data recording; phthalocyanines have many desirable attributes suitable for use in optical data storage.

Data Display

In recent times, there has been a significant development of display technologies which can

interface with an ever-increasing number of electronic devices. The role of the display is simply to render the output from the device in a form that is intelligible to the human reader; examples of devices include computers, calculators, watches, televisions, public signboards, etc.

Cathode Ray Tube

For many decades, the cathode ray tube (CRT) was the most common display used for televisions or visual display monitors. The operating principle in CRT involves an electron beam that is generated from a cathode located at one end of a glass vessel, which is held under vacuum. The electron beam is accelerated and is then moved horizontally or vertically using electrostatic or electromagnetic means. The inner, front surface of the glass vessel is coated with inorganic phosphors, and, when the beam of highly accelerated electrons hit this surface, the phosphors emit visible light. This process is known as *cathodoluminescence* which is an emissive technology and therefore produces bright images.

Liquid Crystal Display

Because of the large bulk and mass of CRTs, liquid crystal displays (LCDs) have been developed. LCDs employ specific organic molecules, such as *para*-cyanobiphenyl, which can be readily aligned in an electrical field. When the molecular axis of *para*-cyanobiphenyl is orthogonal to a beam of polarized light, the light is absorbed and a dark color results. When its molecular axis is parallel to the direction of the light beam, no absorption occurs and a pale-colored area results. This contrast allows monochrome imaging. Neither CRTs nor LCDs are the most suitable technology for very large area displays, where other display techniques such as plasma panels and electroluminescent devices offer advantage.

Organic Light-Emitting Devices

Organic light-emitting devices (OLEDs) are one of several technologies available for use as emissive flat panel displays. OLEDs possess the advantage that their molecular properties can be tailored, as well as inherent potential low cost, low

voltage operation, and relative simplicity of processing and fabrication into devices.

Two types of OLEDs are being developed: one based on multilayers of vapor-deposited, low molecular weight materials and other on polymeric materials, either by precursor polymerization or by casting from solution and subsequent processing. Most research has been done on low molecular weight material OLED.

A wide variety of low molecular mass materials have been designed for high-performance materials. The hole-transport layer (HTL) materials are normally substituted aromatic amines, which are known to have high hole mobility and which are applied to the surface of a glass substrate which has been coated with the conducting transparent material, indium tin oxide. The electron-transport layer (ETL) materials commonly used are emissive metal complexes, commonly aluminum, beryllium, or lanthanides. Some ETL materials are chosen because they are non-emissive so as to act as combined ET and hole-blocking layers.

Polymeric LED materials are a more recent development and have many attractive properties. One prime advantage is the ease with which it is possible to lay down thin films on large areas of a substrate either by spin coating or dip coating. Typical polymers are the green poly(*para*-phenylene vinylene) (PPV), the orange-red dialkoxy derivatives, and the blue polyfluorene.

Energy Transfer

Energy transfer via functional dyes involved in electronic materials has been discussed above. In this section, organic semiconductors and solar cells will be considered.

Electroluminescence (EL) involves the conversion of electrical energy into nonthermal light. To achieve this conversion, the materials can be either inorganic or organic. *Low-field* devices comprise conventional light-emitting diodes (LEDs), which are constructed from monocrystalline semiconducting materials.

Organic semiconductors are used in numerous devices, including field-effect transistors, light-emitting diodes, Schottky diodes, photovoltaics

(solar cells), light-emitting electroluminescent devices, etc. Organic semiconductor devices have been studied as unipolar devices based on hole-transport materials, because of the lack of suitable electron-transport materials. Conventional semiconductor LEDs are made by growing a region of *n*-type semiconductor material which has been doped with donors and *p*-type semiconductor materials doped with acceptors.

Organic Semiconductor

Organic semiconductors can be small molecules or polymers as employed in the case of electroluminescent molecules for emissive displays. Hole-transport materials include oligo- and polythiophenes, poly(thienylene vinylenes), and pentacenes. Electron-transport materials include copper phthalocyanine, hexadecafluoro copper phthalocyanine, naphthalenetetracarboxy dianhydride, and perylenetetracarboxy dianhydride.

Solar Cells

Solar cells have enjoyed much interest, especially in recent times. Attempts to mimic photosynthesis using chemicals closely related to chlorophyll such as phthalocyanine constitutes have received interest. However, the efficiency of most solar cells, including those based on silicon, is very low and requires improvement in order for solar cells to make a real impact.

Most recent research is focused on dye-sensitized solar cells (DSSCs) which provide both technically and economically viable alternatives to present-day photovoltaic devices. In DSSCs, the two processes of light absorption and charge carrier transport are separated, contrary to conventional systems. Light is absorbed by the *dye sensitizer* which is anchored to the surface of a wide-bandgap semiconductor. Charge separation takes place at the interface via photo-induced electron injection from the dye into the conduction band of the solid. Carriers are transported in the conduction band of the semiconductor to the *charge collector*. Relatively inexpensive semiconducting materials are used, such as titanium dioxide, zinc oxide, and tin oxide; various dyes are used.

DSSC technology has been used as an energy provider for devices using electron chromic cells in smart windows and display.

Nonlinear Optical Dyes

Nonlinear optics (NLO) is concerned with the interaction of electromagnetic radiation with various media to produce new radiation that is altered in phase, frequency, and amplitude from the incident radiation. Electrooptical activity, applying a field to change the refractive index of a material, means that the incoming light can be manipulated from on path to another.

While there are several types of nonlinear effects, the most important is *second-order frequency doubling*, whereby the incident radiation is converted to radiation of double the frequency; this has many applications in both telecommunications and optical data storage. For example, since in telecommunications the most efficient way to transmit data is via infrared laser radiation, consequently, an important use of nonlinear optical materials would be to convert the infrared radiation to visible radiation by frequency doubling, thus enabling easier detection of the signals. An example in optical data storage is that frequency doubling would enable more data to be stored per unit area because of the smaller spot size of the frequency-doubled radiation. Molecules capable of high polarizability give the best NLO effects; in this context, organic molecules having powerful donor and acceptor groups conjugated through a delocalized π -electron system give the largest second-order effects.

Laser Dyes

Although both solid-state and semiconducting lasers have made many inroads into applications that previously were the domain of dye lasers, nevertheless, dye lasers continue to offer several advantages:

- Tunability over a wide range of wavelengths from <400 to 1000 nm.
- Hyperfine tuning.
- High average power in both pulsed and continuous modes.
- High feed power.

- Ideal light source for the generation of short pulses.

Dyes have the important role in dye lasers of allowing a fixed wavelength of laser input to be tuned to a wide range from which a selection can be made appropriate for the desired end use. Modern laser dyes have changed little from those used a decade or so ago; coumarin and xanthene colorants are the two most important colorant types. Recently, dye lasers operating in the spectral region of 600–750 nm have been of particular interest as they have found applications in photodynamic therapy of cancer, medical diagnostics, surgery, dermatology, urology, fluorescent immunoassays, laser isotope separation, and environmental monitoring.

Biomedical Applications

Dyes have a long history of use in biomedical fields both for diagnostic and therapeutic purposes. Many dyes were used for staining bacteria and azo dyes can selectively detect metal cations. Recently, attention has focused on two interrelated aspects of *photomedicine*, namely, *phototherapy* and *photodiagnosis*. Phototherapy concerns the use of ultraviolet, visible white light, or near-infrared radiation to treat a variety of diseases, while photodiagnosis relates to the use of optical methods, based on fluorescence, for early diagnosis.

A vast range of organic chromophoric ring systems exhibit fluorescence. Fluorescence techniques are commonly used in biological, medical, and drug development. As such, fluorescent labels and probes have been employed in immunoassay, fluorescence microscopy, DNA sequencing, detection on arrays, flow cytometry, gel based quantification of nucleic acids and proteins, capillary electrophoresis, and single-molecule detection.

The *fluorophores* used in these analytical and biological outlets are based on cyanines, coumarins, naphthalimides, anthraquinones, acridines, etc.; however, such colorants have to be modified in order to be suitable for labeling purposes, DNA

fluorescence, etc. Cyanines, in particular, are the most popular and extensively researched colorant type for use in biological and medical imaging protocols owing to their excellent synthetic flexibility and fluorescence properties. Indeed, cyanines are the only synthetic, near-infrared fluorophores which are commercially available for use in this area.

Smart Textiles with Photochromic Dyes

A photochromic compound is characterized by its ability to undergo a reversible color change. Many photochromic organic compounds have been found and widely investigated in various fields. Spiropyrans and the closely related spirooxazines are important classes of photochromic dyes. While these two classes of compound are similar in many respects, the replacement of the benzopyran ring with a naphthoxazine ring results in spirooxazines having the advantage of greatly improved resistance to prolonged UV irradiation, which confers greater commercial importance to them. Applying photochromic dyes to a fabric can impart to the fabric “smart” fashion effects as well as enhanced UV protection. In this context, the application of spirooxazines to textiles has attracted research interest [7–11]. When UV light was applied to spirooxazine dyeings, photochromic reactions were mainly observed at 610 nm in which the color intensity of the dyeings increased with irradiation time. The color-produced photomerocyanine form of the colorant is usually unstable and returns to the original spiro form. The color strength (K/S) of the color-produced spirooxazine dyeings decreased with increasing storage.

Dye, Ink-Jet

Algy Kazlauciusas

Department of Color Science, University of Leeds, Leeds, West Yorkshire, UK

Definition

An inkjet dye is a solvent-soluble colorant present in inkjet ink formulations to produce text and photo-realistic images for drop-on-demand piezo and thermal deskjet printers, signage for continuous industrial inkjet printers, and all manner of designs for piezo and thermal inkjet textile printers.

Principal Applications

Dyes used for inkjet printing can be placed into three categories:

- (a) Deskjet photo printing (A4 and A3 formats) of photo-realistic images, using drop-on-demand piezo and thermal inkjet systems

Paper substrate materials containing ink-specific ink-receivable layers are used, with both dye and pigment colorants being utilized.

Wide-format printing of images onto paper substrates (Giclée prints), using *Iris Graphics* printers, was the dominant method for producing large format photo-realistic fine art prints during the 1980s and early 1990s. These printers employed dye-based ink formulations to produce images. However, these printers have long been replaced by a range of wide-format printers capable of producing images on a range of substrate materials, including paper, poly(vinyl chloride), and poly(propylene). This new breed of printer type uses pigments as the colorant in all ink formulation types, i.e., water-based inks, solvent-based inks, and UV curing inks. The dyes which previously had been employed for large format images, especially for outdoor purposes, were replaced with pigments because of the inferior light fastness of the dye prints.

- (b) Industrial inkjet printing

This area is associated with continuous inkjet printing that is used for high-definition coding on a range of substrates, bar codes, micro printing, logos, special characters and graphics. For this type of inkjet printing, solvent dyes are heavily utilized. In addition, this category also encompasses piezo micro drop-on-demand and large character, valve jet technologies. For these latter types of printing, highly dispersed pigments are favored.

- (c) Printing of fabrics

Both dyes and pigments are used for the printing of textiles, with reactive dyes primarily used for cotton, viscose, and other cellulosic fabrics; acid dyes for silk, polyamide, and wool; disperse dyes for polyester; and pigments for a wide range of different fabrics.

Deskjet Photo Printing

In the early days of deskjet printing, prior to the advent of photo-realistic imaging, both thermal and piezo drop-on-demand printers used aqueous dye-based inks only. The first-generation dyes utilized were commercially available direct and acid dyes produced for the textile market as well as food dyes [1–5]. As prints produced using vibrant colors, as opposed to dull colors, are far more attractive to the average observer, it is no surprise that the early dyes used were chosen primarily for their vibrancy. Typical dyes chosen were C.I. Acid Yellow 23 (monoazo), commonly known as tartrazine, C.I. Acid Red 52 (xanthene), and C.I. Acid Blue 9 (triphenylmethane) with C.I. Food Black 2 (disazo) chosen as the black dye [6]. Unfortunately the vibrancy of these dyes was seriously offset by the poor light fastness of the ensuing prints. Subsequent dye introductions included azo H-acid dyes such as C.I. Reactive Red 180 for the magenta component, the phthalocyanine dye C.I. Direct Blue 199 for the cyan, C.I. Direct Yellow 132 as an alternative yellow, and metalized C.I. Reactive Black 31 for the black component. It should also be noted that for a number of deskjet ink sets, aimed at the photo-realistic imaging market, C.I. Pigment Black 7 (carbon black) was utilized instead of a black dye.

At the time, deficiencies in the inks including limited water solubility and insoluble impurities such as salts were addressed by replacing strongly acidic sulfonic acid groups with weakly acidic carboxylic acid groups so as to give high solubility in alkaline inks and by the use of dialysis/ultrafiltration purification techniques to remove insoluble impurities. At this point in time, the key properties required of inkjet dyes for photo-realistic imaging are brilliant/vibrant colors; high resolution; low color bleed (ideally none); high color strength; 5–20% solubility; very low salt content (chloride, sulfate, calcium, and iron all less than 50 ppm); good fastness to light, water, and smear; thermal and chemical stability; high surface tension; nontoxicity; and good storage stability at extremes of temperature.

Further key aspects in the drive to rival silver halide images were the introduction of light magenta and light cyan inks to improve skin tones and the gradual development over time of ink-substrate compatibility using ink-receivable layers, namely, swellable polymer (based on polyvinyl alcohol, gelatin, etc.) and pigmented microporous (silica/alumina), coated onto a conventional photographic resin-coated paper base [7–9].

A further development in the late 1990s was the introduction by Epson of the first pigment-based desktop inkjet printer. While this was a further attempt to improve the light fastness of photo-realistic images, other image attributes were sacrificed, namely, a reduced color gamut, the propensity to bronzing, and metamerism problems.

Currently deskjet, photo-realistic, inkjet printing principally uses anionic water-soluble dyes, incorporating sulfonic/carboxylic acid groups to ensure solvent solubility [10, 11]. With respect to Colour Index dye classification, these include acid dyes, direct dyes, and passivated reactive dyes [12]. The general approach, when used with the more commonly available microporous ink-receivable layer, is that the anionic dyes are attracted to the cationic polymers that modify the surface of the silica/alumina particles.

Table 1 highlights the more commonly used water-soluble dyes that are commercially available for photo-realistic deskjet printers [13, 14]. The table has been assembled with the aid of information gleaned from the Society of Dyers and Colourist's Colour Index and the web sites www.clariant.com, www.pigments.clariant.com, www.nip.clariant.com, and www.dyes.com.

Although pigment-ink photo-realistic printers now tend to dominate the A4/A3 market, due mostly to their light fastness, many photographers still prefer dye-ink prints rather than equivalent pigment-ink and conventional silver halide prints. When Clariant launched their Claria dye-based ink set in 2007, this revitalized the demand for dye-based photo-realistic images, the dyes [15–17] displaying light fastness ratings of at least 6 [18]. A comprehensive survey in 2008 (Zhang) revealed the preference of dye-based prints in the

key performance areas of color gamut, image resolution, and image contrast. Although dye-based inkjet prints were also perceived to be superior to pigment-based inkjet prints, regarding skin tone representation, they were perceived to be inferior to conventional silver halide prints [19].

A review of recent patent literature indicates ongoing research activity with respect to improved performance for dye colorants used for printed images, in the areas of improved image permanence on porous photo media [20, 21], or dye admixtures to extend chroma [22].

Industrial Inkjet Printing

Industrial inkjet printing is primarily utilized on production lines, or in manufacturing processes. Industrial inkjet printers can be broadly classified as continuous or drop on demand, although there are variants within each of these individual classifications.

Continuous printing technology [23] grew on the back of legislative requirements for product identification, i.e., product and data coding. Thus, this type of inkjet technology is commonly used to print the date, together with 1D and 2D bar codes, onto a range of different substrates, e.g., cartons, bottles, and cans. As this type of printer is used on moving production lines, the inks must be able to dry quickly; this is achieved using volatile solvent-based inks. Although the original inks employed were methyl ethyl ketone (MEK)-based, the drive for the minimization of volatile organic compounds (VOC's) has resulted in the introduction of solvent mixtures such as acetone in combination with lactate esters [24].

Although solvent dyes are predominantly used in solvent ink formulations, a number of black inks using carbon black pigment have been developed, specifically for bar code-OCR readability. A key advantage of using dyes for solvent-based inks is the fact that they are able to provide their own conductivity, provided either by a counter ion or via existing residual salts. In addition, dyes also have the advantage over pigments that they are present as a solution rather than as a dispersion. This means that the stability of the ink generally is

superior to an equivalent pigment-based ink, both in storage and when in use in the printhead.

Table 2 shows the most commonly used solvent dyes employed for industrial continuous inkjet printing on a range of different substrate materials. The table has been assembled with the help of information provided by the Society of Dyers and Colourist's Colour Index and a selection of web sites, i.e., www.nip.clariant.com, www.pigments.clariant.com, and www.dyes.com.

Inkjet Textile Printing

Whereas the 1990s were key years for the development of both deskjet and wide-format inkjet printing with respect to photo-quality images onto IRL-coated paper substrates [25], inkjet textile printing did not become a widespread

commercial proposition until 2003, when several inkjet industrial printers were launched at ITMA (International Textile Machinery Association), Birmingham, UK. One key aspect of these printers was the introduction of higher-resolution printheads.

While the market for digital textile printing continues to grow, the pace of growth is not dramatic, with digital printing, accounting for only 1% of the total output of textile printing technologies [26]. However, inkjet textile printing is suitable for short runs, small batches, and “just in time” production, making it ideal for upmarket textile items such as luxury home furnishings, fashion dress, and fashion accessories. As Italy is acknowledged as the major area for the production of high-end textile printing in Europe, a high percentage of commercial digital inkjet systems are located within this region. Although major

Clariant Brochure – products for nonimpact printing/colorants for solvent-based inkjet inks.

technological improvements have been claimed since ITMA 2007 in Munich, further improvements are required, namely, penetration of colorants into the textile substrate, a wider color gamut, the development of a universal ink for all textile substrates, specialty printing, and greater print production speeds [27].

The desired requirements for dye-based inks utilized in digital inkjet printing on textiles are not dissimilar to the requirements needed for inkjet photo-realistic imaging onto ink-receivable layer-coated papers. Key requirements are as follows:

- (a) Good optical density
- (b) Narrow absorption curve
- (c) Minimal color to color bleed
- (d) Good light fastness
- (e) Good water fastness
- (f) High solvent solubility
- (g) Minor levels of inorganic salts (less than 100 ppm chloride and sulfate anions)
- (h) Thermally and chemically stable

It is common practice that inkjet printing onto textile fabrics, using reactive and acid dyes, generally involves pretreatment and posttreatment to ensure dye fixation onto the fabric. There are a number of important reasons as to why the dyes are kept apart from the thickeners and other required chemicals, prior to fabric application:

- (a) Many of the chemicals required for the process could cause corrosion of the inkjet

printhead and/or instigate stability problems in the ink.

- (b) The rheological properties of the thickeners used are incompatible with the printheads
- (c) Reactive dyes may hydrolyze if alkali is present in the ink formulation.
- (d) Large levels of salt in aqueous inks would not only contribute to print-head corrosion but also reduce the level of dye solubility.

Water-based dye inks tend to be specifically used for piezo-electric and thermal printheads and usually contain a glycol solvent as a humectant. As previously mentioned, reactive dyes are used in ink formulations specifically prepared for the printing of cotton, viscose and other cellulosic fabrics. For wool, silk, and nylon fabrics, acid dyes tend to be the norm, whereas for polyester fabrics disperse dyes are used. Huntsman with their Novacron[®] reactive dyes, Lanoset[®] acid dyes, and Terasil[®] disperse dyes are a major supplier of digital inkjet dye-based inks. Other key companies involved in producing these inks are Dupont, with their Artistri range of dye-based inks, along with DyStar, Kiian, Sensient Technologies, and Kolorjet.

To ensure dye fixation, steaming under atmospheric pressure at just over 100 °C is required for both acid and reactive dyes. However, for the fixation of disperse dyes, a higher temperature of 170–180 °C is required, although this can be lowered to between 130 and 150 °C if pressure steaming is employed.

Other less popular methods of dye-based inkjet printing on textiles are still in use, namely, solvent-based, oil-based, and phase change. Hot-melt inks are involved in the phase change method, with the inks being solid at room temperature and fluid when heated to between 60 and 125 °C. Piezo printers tend to be used for this method of printing, and the ink vehicle is a mixture of fatty carboxylic acids and alcohol. Solvent dyes utilized are soluble in the vehicle and hence hydrophobic.

A wide range of research activity within the field of digital inkjet printing onto textile fabrics continues to be published, indicating a healthy future. The research areas involved include the development of both new and modified reactive dye structures for inkjet printing [28–30], fabric pretreatment [31, 32] and thickeners [33], development of inks using natural dyes [34], dye aggregation/interaction with water-soluble polymers [35], and new azo pyridone disperse dyes [36].

Dye, Metal Complex

J. N. Chakraborty

Department of Textile Technology, National Institute of Technology, Jalandhar, Punjab, India

Synonyms

Premetallized acid dyes

Dye, Metal Complex,

Fig. 1 C.I. Reactive Violet 1

Definition

Metal-complex dyes and pigments are the coordination complexes of bi- or polyvalent transition metal ions with various dyes and have versatile application in various fields, which include the dyeing of nylon and protein fibers, paint, toners for photocopiers, laser and ink-jet printers, photoconductors for laser printers, nonlinear optics, singlet oxygen generators, dark oxidation catalysts, and high-density memory storage devices.

Chemistry and Application

Coloration of Textiles

The most prevalent examples are monoazo (C.I. Reactive Violet 1, Fig. 1) and disazo (C.I. Reactive Blue 82, Fig. 2) dyes. While formazan dyes are bi-, tri-, and tetradentate complexes, only tetradentate copper complex formazan dyes (e.g., C.I. Reactive Blue 160, Fig. 3) have found commercial use owing to their intense colors [1].

Metallization imparts a bathochromic shift producing deeper but duller shades. The spectra of 1:1 metal-complex azo dyes display narrower curves, while that of 1:2 complex dyes show a broader curve exhibiting blueness and dullness (Fig. 4).

1:1 metal-complex azo dyes are stable in strongly acidic pH and are preferably applied to wool, silk, and nylon fibers at a low pH (<4); they exhibit low to moderate coverage of fiber irregularities and poor compatibility in mixture. In contrast, 1:2 complexes are stable in weakly acidic pH and hence are applied from weakly acidic or neutral dyebaths (pH ~ 5–7); they display good buildup on wool, silk, and nylon fibers, exhibiting

Dye, Metal Complex,**Fig. 2** C.I. Reactive

Blue 82

C.I. Reactive Blue 71 (Fig. 12) are used in the coloration of paper and cotton, respectively.

Ink-Jet Printing

Ink-jet inks are water-soluble dyes in an aqueous vehicle. Metal-complex dyes and pigments possessing high absorbance, high chroma, and excellent lightfastness are employed. The copper complex dye C.I. Reactive Black 31 (Fig. 13) is very widely used as black in almost all ink-jet printers. For ink-jet printing of black on textiles, the 1:2 complex of a chelating azo dye with a mixture of metals “M” ($M = Cr^{3+}/Co^{3+}$, 70:30) is extensively used [8], as exemplified by C.I. Reactive Black 8 (Fig. 14).

The black phthalocyanine dye (Fig. 15) was developed through reaction of amino phthalocyanine with acrylic or methacrylic acid, where “M” represents metal or hydrogen and “R” hydrogen or methyl. Solvent-soluble chromium-complexed azo black dyes, a mixture of 4- and 5-nitro, such as C.I. Solvent Black 35 (Fig. 16), is used in hot melt ink-jet printing [9].

Though yellow and magenta azo dyes are metal-free, the copper complex azo dye, C.I. Reactive Red 23 (Fig. 17), and the nickel complex PAQ dye (Fig. 18), where $R = H, Cl$, or $COOH$ and $R' = SO_2NHalkyl$, display dull and bright colors, respectively, each with similar high light fastness (Fig. 17) for ink-jet printers [10].

Copper phthalocyanine is extensively used as cyan for ink-jet printing; for textile ink-jet printing, metallized reactive dyes are used [8], such as C.I. Reactive Blue 71 (Fig. 12).

Photoconductors for Laser Printer

Photoconductors are dual-layer devices, and are exclusively used in laser printers. Metal-complex dyes, especially titanyloxy-phthalocyanine

**Dye, Metal Complex, Fig. 3** C.I. Reactive Blue 160

high compatibility in mixtures [2]. Dyeings of chromium complex dyes display high overall fastness compared to those obtained using copper, cobalt, and nickel complexes [3]. The metal remains bonded to the lone pair with one of the azo nitrogen atoms and not to the p-bond of the azo group in 1:2 copper complex dye (Fig. 5) [4]; however, in 1:1 copper complex dyes, the symmetrical dihydroxyazo ligand (Fig. 6) forms the 1:1 square planar complex (Fig. 7) [5].

Copper phthalocyanine (Fig. 8) is a bright blue pigment of λ_{max} 660nm characteristically displaying very high all-round fastness and it exists in several polymorphic forms [6, 7]. The redder, α -metastable form is preferred for use in paint, whereas the greener, stable β -polymorph is employed in printing inks. Complete chlorination of azo phthalocyanine blue pigment (Fig. 9) produces the high fastness green pigment, C.I. Pigment Green 7 (Fig. 10).

Water-soluble phthalocyanine dyes possess either sulfonic, sulfonamido, or both types of solubilizing group and are useful for the ink-jet printing of textiles. C.I. Direct Blue 199 (Fig. 11) and

(Fig. 19), can act exclusively as charge generation materials (CGMs) in photoconductors [11]. All modern laser printers use titanyloxy-phthalocyanine, type IV polymorph, as the CGM possessing a “shallow shuttlecock” shape has a subtle effect on the packing of the molecules [12]. The pigment used as the photoconductor must be extremely pure and possess the correct morphology.

Toners for Photocopiers and Laser Printers

Laser printers, photocopiers, and especially ink-jet printers employ metal-complex dyes as toner. Laser printers and photocopiers use electricity and light to form an image with the help of a photoconductor; the latent electrostatic image on the photoconductor is thermally fixed using a toner [11, 12]. Metal-complex dyes and pigments produce the positive hole in the organic photoconductor and also perform key functions in

Dye, Metal Complex, Fig. 11 C.I. Direct Blue 199

Dye, Metal Complex, Fig. 12 C.I. Reactive Blue 71

Dye, Metal Complex, Fig. 13 C.I. Reactive Black 31

both the image generation stage and the toner development stage of the reproduction process.

Two main types of colored molecules are used in a toner: a colorant is employed to impart color to the toner, and the charge control agent (CCA) imparts color as well as control the triboelectric charge on the toner particles. Copper phthalocyanine, C.I. Pigment Blue 15:4 (Fig. 8), is the cyan colorant; however, pigments used for the yellow and magenta colorants are metal-free. CCAs can be either colored or colorless and are mainly metal-complex dyes. Colorless CCAs are useful for yellow, magenta, and cyan toners, while colored CCAs are more effective than colorless agents but are restricted to black toners. CCAs that impart a negative charge to the toner are invariably metal complexes, particularly 1:2 chromium-complexed azo dye with a mixture of 4- and 5-nitro (Fig. 16) and another one with a mixture of 4- and 5-chloro [12]. Efficient, colorless, negative-charging CCAs were developed by producing colorless analogues of 1:2 chromium complex of an aromatic *ortho*-hydroxy carboxylic acid, such as the complex of di-*tert*-butyl salicylic acid, e.g., *Bontron E-8136* (Fig. 20).

Another important class of supramolecular metal-complexed pigments is the so-called toner

Dye, Metal Complex,**Fig. 14** C.I. Reactive

pigments which are water-soluble azo dyes containing sulfonic acid groups and are insolubilized by complexing with a divalent cation, such as calcium and barium. These compounds provide the standard magenta colorants for printing inks, such as C.I. Pigment Red 57:1, known as *Calcium 4B toner* (Fig. 21); chlorination of this product develops the red pigment which is suitable for characterization by synchrotron radiation.

Dark Oxidation Catalysts

These are organometallic complexes based on transition metals possessing variable oxidation states and are used as **chemical transformers**

Dye, Metal Complex, Fig. 17 C.I. Reactive Red 23

Dye, Metal Complex, Fig. 19 Titanyloxy phthalocyanine

Dye, Metal Complex, Fig. 22 Organo-manganese complex (Unilever)

and in laundry powders [13]. Manganese complexes were developed and marketed, respectively, by Proctor and Gamble and Unilever, as washing powders [14–16]. Unilever's manganese complex (Fig. 22) was effective in removing dirt and stains from soiled fabrics, but this was accompanied by serious damage of the fabric. Proctor and Gamble developed a similar dark oxidation catalyst, manganese phthalocyanine tetra-sulfonic acid (Fig. 23), but could not achieve commercial success because of the “manganese factor” which

was probably at the root of disintegration of the fabric.

Singlet Oxygen Generators

These have multipurpose applications, such as in skin, breast, and oropharyngeal cancer treatment through photodynamic therapy (PDT) using a photosensitizer [17, 18]. In photodynamic therapy, electromagnetic radiation in the visible and adjacent ultraviolet and infrared regions is used for photochemical treatment of (i) jaundice (neonatal hyperbilirubinemia) in the newborn, and especially in the prematurely born, (ii) psoriasis using light in the UV-A range and an administered photosensitizer, (iii) wet form of

Dye, Metal Complex, Fig. 23 Manganese phthalocyanine tetra-sulfonic acid (Proctor and Gamble)

Dye, Metal Complex, Fig. 25 Tinolux BBS

Dye, Metal Complex, Fig. 24 Sulfonated of chloroaluminum (III) phthalocyanine (Photosens)

Dye, Metal Complex, Fig. 26 Hexa-deca-fluoro copper phthalocyanine

age-related macular degeneration with a photosensitizer as well as a laser light source, and (iv) certain cancer, such as skin, breast, and oropharyngeal cancer with a photosensitizer and red light [19–24].

The phthalocyanine-based commercial product *Photosens* (Fig. 24) is a widely used photosensitizer prepared by the direct sulfonation of chloroaluminum (III) phthalocyanine. Singlet oxygen generators are also used as hard-surface disinfectants, soaps, washing powders [25], and insecticides [26]. These eco-friendly photo-bleaches convert triplet oxygen ($^3\text{O}_2$) into highly reactive singlet oxygen ($^1\text{O}_2$) in the presence of light, thus acting swiftly to bleach stains. The blue aluminum phthalocyanine dye, *Tinolux BBS* (Fig. 25), is a commercial singlet oxygen generator [27]; zinc phthalocyanines, which absorb in the near-infrared region at ~ 725 nm, are also very good singlet oxygen generators [28].

Organic Semiconductors

Organic semiconductors are used to fabricate electronic devices. Metal-complex pigments, such as hexa-deca-fluoro copper phthalocyanine (Fig. 26), are used for electron transport [28].

Infrared Absorbers

Upon complete chlorination, blue copper phthalocyanine is converted into its green-colored, fast pigment which also is an efficient infrared absorber, possessing high solubility in organic solvents and displaying narrow absorption curves at around 780 nm. Phthalocyanines containing amino donors, in combination with either thiols [29] or halogens [30], provide broader curves absorbing at around 900 nm.

Copper phthalocyanine loses its planar structure upon conversion to infrared absorber, with eight of the sterically demanding thiophenol groups lying above the plane of the

phthalocyanine ring and eight lying below. Taking advantage of this feature, non-planar copper phthalocyanines are used as high-level security components in currency notes [31, 32], in computer-to-plate technology to convert near-infrared radiation into heat [33, 34] and as solar screens on car windscreens and windows of buildings which allow daylight through but screen out infrared radiation component which generates heat [35]. However, as the durability of non-planar copper phthalocyanine is not high, palladium phthalocyanine (Fig. 27) is the leading phthalocyanine infrared absorber for CD-R applications [35, 36].

Silver Halide Photography

Metal-complex azo dyes are used in color diffusion transfer photography, employing non-diffusible, magenta dye-releasing colorants which, upon development of the silver halide layer, release a diffusible magenta dye; the nickel

Dye, Metal Complex, Fig. 27 Brominated tetra (α-2,4-dimethyl-3-pentoxy) palladium phthalocyanine

Dye, Metal Complex, Fig. 28 Nickel complex PAQ dye retaining CAR (Ballasted carrier moiety)

complex PAQ dye (Fig. 28), where “CAR” denotes Ballast-Carrier-Link, is a typical example [37]. Other metal-complex azo dyes include pyridylazonaphthols [38] and pyridylazoaminophenols [39].

Nonlinear Optics

Metal complexes, mostly of δ -transition metals, can exhibit nonlinear optical (NLO) behavior which can be used to manipulate the fundamental properties of laser light beams, thereby facilitating optical data processing and storage [40–42], and offering possibilities for the combination of quadratic (second-order) and cubic (third-order) NLO properties along with other molecular electronic properties. Examples include bimetallic complexes containing pyridyl carbonyl centers with ruthenium σ -acetylide; ferrocenyl (Fc) electron donor groups can also exhibit NLO properties [43–45].

In metalloporphyrin derivatives, such as metallophthalocyanines and metallo-2,3-naphthalocyanines, metallation greatly enhances the cubic responses of the compound; such materials often exhibit strongly absorbing, long-lived triplet excited states. Asymmetrically substituted metalloporphyrin derivatives can exhibit extremely large quadratic NLO responses; the β -response of the Cu(II) complex shows a marked wavelength dependence, while its Zn(II) analogue displays essentially identical β 830 and β 1064 values [46].

Some porphyrin-like metal complexes, mostly of Cd(II), in which one of the pyrrole rings is replaced with an aryl or vinyl group, exhibit very large cubic NLO responses [47, 48].

High-Density Memory Storage

The electrochromism exhibited by metal-complex dyes in the near-infrared region (NIR) of the spectrum (ca. 800–2,000 nm), obtained by the generation of different electronic absorption bands, enjoys applications such as optical data storage (ODS) on various disk media, i.e., read-only, write-once, and rewriteable media [49, 50]. In such applications, a layer of a metal-complex dye based on highly conjugated ligands displays a significant absorption maximum which is either at or very close to the wavelength of the laser light and also has relatively low optical absorbance and high reflectance at the recording wavelength and is interposed between the substrate and the reflecting layer of a CD. With appropriate optimization of the optical properties, this composition will record and reproduce [35, 51, 52].

Though polymethine, porphyrin, triphenylmethane, and azoic metal-complex dyes possess good photostability and absorption in the range 750–850 nm exhibiting electrochromism, phthalocyanine (Fig. 29), naphthalocyanines, and cyanine dyes based on indole and benzindole are the most widely used for the mass production of on-disk-structure (ODS) media because of the simplicity of modification, excellent photostability, and cost-effectiveness. However, selective metal-complex dyes should meet certain requirements; partial bromination allows fine-tuning of the film absorbance and reflectivity [35, 49, 53], commercially known as *Supergreen*. Phthalocyanine dyes are not suitable for DVD-R media, since the main chromophore cannot readily be modified to produce a sufficiently large hypsochromic shift; dyes potentially suitable for DVD-R include metal azo complexes, quinophthalones, and

diphenylmethanes. The cyanine dyes are very useful for all current optical disk recording applications [35].

A novel rewriteable optical disk comprising a Si-naphthalocyanine dye and the conductive polymer polythiophene as the recording layer has been reported which could be played back on conventional CD players, even after ten cycles of rewriting [54]. The phthalocyanine derivative has recently been reported to be capable of recording high-quality signals at high speeds [55].

A series of metallized thiazolyl-azo dyes with a hydroxy substituent ortho to the azo linkage shows apparently promising performance [56, 57]. Zn(II) complex dyes possess solubility, thermal stability, and suitable absorption at 635 nm and are used as DVD-R dyes [58].

Dye: Photodynamic Therapy

Mark Wainwright

Pharmacy and Biomolecular Sciences, Liverpool
John Moores University, Liverpool, UK

Definition

Photodynamic therapy may be thought of as a directed and controlled application of the cellular

damage possible from light energy. There are two main areas of clinical interest, these being the *photodynamic therapy* of cancer (shortened to PDT) and the parallel application to microbial disease and infection control, the latter having several names, including *photodynamic antimicrobial chemotherapy* (PACT, used in this review), *antimicrobial photodynamic therapy* (APDT), and *photodynamic disinfection* (PDD). For both areas of clinical interest, in order to target and mediate cellular damage, a light-absorbing chemical, called a *photosensitizer*, is employed.

In both the anticancer and antimicrobial guises, the underlying science is the same, namely, (i) uptake by or association of the target cell with a photosensitizer, (ii) illumination of the target cell and the concomitant electronic excitation of the photosensitizer, and (iii) chemical reaction of the photosensitizer with its biomolecular environment or energy transfer from the photosensitizer to a local oxygen molecule. In both of these final scenarios, reactive oxygen species result which are highly toxic in the cellular environment (Fig. 1). The combination of locally administered photosensitizer and targeted delivery of illumination results in the production of a rapid, destructive

Dye: Photodynamic Therapy, Fig. 1 Photosensitization pathways

local effect by means of which local therapeutic control can be maintained that is absent of side effects in parts of the body remote from the treatment site.

Introduction

The interaction of light and matter is an ordinary, everyday occurrence, so much so that it is ignored by the majority. However, without the effects caused by solar radiation on plant species, there would be no life on planet Earth. Despite the perceived simplicity of plant life, photosynthesis, the process by which plants absorb light and store the energy in the form of carbohydrates, is a complex sequence of chemical interaction and energy transfer. This process is, of course, a positive use of light energy. The converse may be seen in the increasing incidence of skin cancers, usually in those individuals who, unwittingly or not, allow parts of their skin structure to be damaged by the higher energy portion of sunlight or by the radiation provided by sunbeds.

Photosensitizers and Photodynamic Therapy (PDT)

Ideally, PDT involves the use of a nontoxic photosensitizer which produces a damaging effect in the target cells upon illumination. In practice, this has proved elusive, because of either inherent or “dark” toxicity or lack of selectivity for target cells. However, in comparison to conventional chemotherapy or radiotherapy, PDT offers considerable advantages, mainly due to any side effects experienced being localized to the area of application. Compared to surgical excision, the demonstrable advantage of the PDT approach lies in much improved cosmesis, i.e., a lack of tissue damage, disfigurement, and scarring. This can be particularly important, for example, in head and neck cancers, from an aesthetic point of view, and also in external gynecological cancers due to loss of functionality and impaired sex drive.

Photosensitizers Used in PDT

Much of the original work which suggested photodynamic therapy as an approach to malignant disease was due to clinical findings, for example, Policard’s observation of the fluorescence of porphyrins in the blood supply of tumors under fluorescent light during surgery [1]. The porphyrin species involved were naturally occurring species, normally present in the blood. Later work, by Lipson and others, utilized porphyrin compounds derived from bovine blood and thus known as hematoporphyrins or hematoporphyrin derivatives (HpD; see Fig. 2). These were mixtures of short chains (oligomers) of hematoporphyrins (Fig. 2), and their constituency was variable by means of chemical derivation. However, despite the lack of purity entailed, HpD was shown to be reasonably effective in “shutting down” tumors via oxygen starvation, and purer forms, such as “porfimer sodium,” have been licensed clinically for a range of presentations. The main side effect associated with such photosensitizers derives from a lack of selectivity when administered systemically, which has often led to generalized patient photosensitization – i.e., a strong reaction to normal daylight, posttreatment.

So-called “second-generation” photosensitizers related to porphyrins for use in PDT include the chlorins mTHPC and chlorin e_6 (Fig. 2). Both of these agents offer the advantage of longer-wavelength light absorption than their predecessors, due to the marginally altered ring system (one carbon-carbon double bond is missing). However, nonoptimal tumor selectivity was again identified as a problem (with consequent generalized photosensitization as recounted above), and the search for improved photosensitizers has continued, producing new compounds related to the original porphyrins, but with variations on the size and constitution of the ring system [2].

Understanding of the heme biosynthetic pathway has led to the use of a natural porphyrin precursor, 5-aminolaevulinic acid (ALA, Fig. 2), and its derivatives in PDT. ALA is normally utilized in mammalian cell heme (protoporphyrin IX, PPIX, Fig. 2) synthesis, but the increased

Dye: Photodynamic Therapy, Fig. 2 Porphyrin photosensitizers used in PDT. *DHPE* dihematoporphyrin ether, a constituent of HpD and porfimer sodium; *ce6* chlorin e₆;

mTHPC *meso*-tetra(*m*-hydroxyphenyl)chlorin; *ALA* 5-aminolaevulinic acid, a precursor of protoporphyrin IX (PPIX)

metabolism exhibited by tumor cells means that reasonable ratios of the resulting photosensitizer are possible between normal and tumor cell populations. Local application of ALA-containing creams and optimized incubation times have produced excellent therapeutic outcomes in several forms of skin and soft tissue malignancy. As might be imagined, local application of photosensitizers in PDT does not result in the generalized photosensitivity reported with systemic administration as mentioned above.

Apart from porphyrin-type photosensitizers, the main other chemical class employed for clinical PDT is based on the phthalocyanine group. As may be seen from Fig. 3, this class of photosensitizer is structurally related to the porphyrins covered previously, but the phthalocyanines have no naturally occurring lead compounds and are an entirely synthetic class of photosensitizer. Originally discovered during industrial aromatic dye

synthesis in the 1930s, phthalocyanines were accidentally produced via the interaction of phthalic acid, ammonia, and copper from the reaction vessels, copper phthalocyanine being the first example of this type of pigment.

Phthalocyanine derivatives offer a considerable advantage over many previously used porphyrins in exhibiting significantly increased intensity of light absorption coupled with extension of absorption into both the red and near-infrared regions of the visible spectrum. Although the dye chemistry required for phthalocyanine production is well established, this is based industrially on the original copper phthalocyanine, which is an extremely stable blue pigment – thermally, chemically, and photochemically. The characteristically high photochemical stability of this class of photosensitizer is attributable to the presence of the central copper(II) ion, which has a paramagnetic electronic configuration. This

Dye: Photodynamic Therapy, Fig. 3 Phthalocyanine derivatives for PDT

provides a rapid deactivation route for the photo-excited singlet state (see Fig. 1), and consequently, insignificant amounts of reactive oxygen are formed which might otherwise decolorize the pigment. Phthalocyanine research for PDT purposes has therefore been concentrated on derivatives having diamagnetic central metal ions such as zinc or aluminum.

In most cases, phthalocyanines for colorant end use are produced as pigments. Since solution formulations are the norm in clinical use, the inclusion of suitable solubilizing chemical groups has been a significant area of development for PDT-useful derivatives. A small amount of liposomal formulation has been also used for tumor delivery of the non-functionalized material.

To produce readily aqueous-soluble phthalocyanine dyes, metallophthalocyanines may be directly sulfonated. Conversely, phthalic acid derivatives bearing water-solubilizing groups (e.g., sulfonic or carboxylic acids) may be employed. In both of these approaches, the derivatives produced are mixtures by degree of functionality and isomeric constituency. While this is acceptable in commercial dyes, it is not in pharmaceutical development – significantly, a major argument against the continued use of hematoporphyrin derivatives remains their lack of chemical purity. However, a sulfonated mixture based on chloroaluminum phthalocyanine (*Photosens*, Fig. 3) has been in use in the former Soviet Union.

The problem of isomeric functionality has been overcome via the use of subphthalocyanine chemistry (Fig. 3), allowing the introduction of mono-functionality in the ring system, and via the use of a reactive central atom such as silica, which may be functionalized both above and below the plane of the ring (e.g., Pc4, Fig. 3).

Necrosis/Apoptosis

The majority of photosensitizers employed in PDT are either negatively charged or neutral molecules which are generally oil soluble to a significant degree (lipophilic). In many cases, this means that they are extensively bound to blood lipoproteins and, consequently, concentrate in the tumor vasculature. Illumination of the tumor site at this stage thus leads to vascular damage and occlusion, starving the tumor of oxygen.

Direct damage to the tumor itself requires uptake into tumor cells. Illumination then either causes cell death by general, nonspecific oxidation, leading to tumor necrosis, or by programmed cell death (apoptosis). The latter route is more complex and involves an initial damaging event, e.g., to the lysosome or mitochondrion which then triggers intracellular messengers such as the caspases and leads to a cascade of internal processes and cell death.

Treatable Cancers

Initially, the main – and logical – target for PDT was skin cancer, given the ease of application of both photosensitizer and light to such presentations. However, the adoption of fiber optics allowed a rapid expansion of the approach into deeper-seated disease. Similarly, advances in photosensitizer design produced derivatives, as noted above, with extended light absorption characteristics. These provided a more efficient use of light since the longer wavelengths required (≥ 660 nm) lie outside the absorption spectra of endogenous absorbers such as heme and melanin. Table 1 provides an overview of the range of treatment available for malignancy and premalignancy.

Photodynamic Antimicrobial Chemotherapy (PACT)

The negative effect of illumination on a stained microorganism was first demonstrated by Raab in 1900, thus predating PDT [3]. However, while porphyrin-based PDT has become a significant clinical field, the application to microbial pathogens has taken over a century even to become a clinical reality on a small scale. The main reason for this is the straightforward access to effective “conventional” antimicrobial agents enjoyed by the affluent countries of the world over the past 60 years. Only in the twenty-first century, with the waning efficacy of many drugs, is there a requirement for alternative approaches to infection control, particularly in view of bacterial resistance to conventional drugs [4], such as penicillins and tetracyclines.

Logically, as PACT uses the same approach as PDT but applied to microbial pathogens, its limitations are similar also. Thus, the photosensitizers employed in or proposed for PACT, known collectively as “photoantimicrobials” due to their extremely broad spectrum of activity, require local or topical application due to the light activation factor. While this might, at first glance, appear to trivialize the approach, as it cannot thus be used for systemic infection, this is not the case. Following the PDT paradigm, localized infection may be targeted anywhere in the body via the use of endoscopy and fiber optics. Indeed, initial forays into the clinic have been made in oral and lung infection, as well as the more obvious dermatological areas, such as acne, ulcers, and nail infection.

Photoantimicrobials

One area of dissimilarity between PACT and PDT lies in the chemical types involved. While PDT has remained firmly based on the porphyrin class from which it was first developed, photosensitizers for use against microbial species require different makeup for broad-spectrum activity. However, it should be noted that, since the metabolism of many bacterial species includes porphyrin synthesis, ALA may be of use here also, used in the same way as detailed above for anticancer PDT.

The use of dyes as chemotherapeutic agents in the first half of the twenty-first century was a result of scientific development of the heavily dye-oriented organic chemistry begun by Perkin, Hoffmann, and others. The first dye to be used clinically was the phenothiazine *methylene blue* (C.I. Basic Blue 9), which was shown to be antimalarial in 1890. The chemical structures of many modern antimalarials, as well as drugs for the central nervous system, have much in common with methylene blue as a consequence, the phenothiazine dye being tested as a treatment for many different illnesses mainly due to its very low toxicity in humans. Methylene blue has also been the lead compound in photoantimicrobial research since it was shown to be active against bacteria, viruses, fungi, and protozoa by various

groups before the mid-1930s. Unfortunately for the field of photoantimicrobial endeavor, 1935 saw the initial clinical release of the first conventional antibacterial agent, sulfanilamide (as *prontosil*) by IG Farben, beginning what has been known to many as the “antibiotic era.” Clearly, effective and easily administered antibacterial agents are more appealing than an approach requiring light activation, and photoantimicrobial research languished as a result.

Unsurprisingly, given the flagrant overuse of our valuable antimicrobial arsenal, drug resistance – particularly in bacteria – has become a very serious clinical problem. Indeed, the problem is increasing to such an extent that many strains of bacteria in our hospitals are approaching indestructibility, as far as conventional antibacterial drugs are concerned. This resistance is merely the outcome of evolution directed by overuse, and misuse, of drugs which have only a single site/mode of action, i.e., which may be circumvented by a single alteration as a result of natural bacterial mutation. One of the advantages of the photoantimicrobial approach is that there are multiple sites and modes of action, making microbial resistance development far less likely.

Broad spectrum, in terms of photoantimicrobial agents, means activity against bacteria, viruses, fungi, and protozoa, and this is generally associated with positively charged (cationic) photosensitizers, such as methylene blue and its derivatives. One of the reasons that the porphyrin photosensitizers utilized in anticancer PDT are not useful leads for photoantimicrobial development is that, as anions, they have little effect on gram-negative bacteria and so cannot be considered to be broad-spectrum agents. However, even this level of activity is massively different to that of conventional antimicrobial drugs, which are *either* antibacterial *or* antiviral *or* antifungal *or* antiprotozoal.

Methylene blue itself is a tricyclic heteroaromatic molecule which absorbs red light in the region of 660 nm. The related dye *toluidine blue* (C.I. Basic Blue 17) absorbs at a shorter wavelength (c. 625 nm), mainly due to the non-alkylation of one of its amino groups (Fig. 4). Both of these photosensitizers produce significant yields of singlet oxygen, both in vitro and in vivo.

Dye: Photodynamic Therapy,
Fig. 4 Phenothiazinium photoantimicrobials

While there have been considerable strides made in synthesizing improved agents with these dyes as lead compounds, the amount of regulatory testing required has so far hindered progress toward the clinic, and methylene blue appears to be the chosen derivative, having been licensed for oral disinfection and blood plasma decontamination in several countries. The extension of such applications to bacterial decolonization and other local anti-infection measures is proposed in order to lessen the burden on conventional antimicrobial delivery, particularly in view of the resistance problem and the dwindling number of agents effective against serious diseases such as septicemia and bacterial meningitis.

Light Sources

Early clinical PDT was carried out normally using in situ hospital lasers, which were expensive both to purchase and to maintain. While the advent of much cheaper diode lasers improved the situation financially, both sources were tied to single-wavelength output and were thus restricted in the number of photosensitizers which might be used. However, both tunable dye lasers and light-emitting diode (LED) sources have revolutionized the area, in terms of adaptability and cost, such that financial considerations present no bar to the adoption of the technique by healthcare concerns. It should be noted that there are still only three photosensitizers generally licensed for clinical use (Table 1).

Treatment of Age-Related Macular Degeneration (ARMD)

Photosensitizers can be used in the treatment of wet, age-related macular degeneration – a condition, normally in the older patient, where new

blood vessels (neovasculature) grow from the back of the eye and break through into the region of the retina containing the rods and cones necessary for the perception of color and shading. The new vessels leak blood and fluid, causing scarring which is associated with a gradual loss of central, but not peripheral, vision.

The concentration of lipophilic, anionic (typically porphyrin-type) photosensitizers in tumor vasculature has been mentioned. This propensity has a positive spin-off in the treatment of wet, age-related macular degeneration. The use of lipophilic, anionic photosensitizers such as chlorin *e*₆ (verteporfin) allows selective targeting and ultimate destruction of the neovasculature.

Dynamics of Color Category Formation and Boundaries

Stephanie Huetter
Department of Psychology, University of
Memphis, Memphis, TN, USA

Definition

Dynamics of color boundaries is broadly the area that characterizes color categorization as a process that occurs over time.

Color Boundaries

A color category boundary is the area in perceptual color space where the labeling of one color transitions into another label. Color is a continuous wavelength dimension but distorted into non-linearly perceived perceptual categories. A category boundary is fundamentally a distortion

of continuous color space during perceptual and cognitive processing of color. There is no external signal in the wavelength dimension to tell the perceptual system to make this abrupt transition. This is called *the problem of invariance* [1]. The demarcation of color space has led to empirical work seeking to characterize color boundaries and discover their underlying dynamics.

There are various tasks that can be used to define a color boundary. One way researchers can do this is simply by presenting a color swatch and asking participants for the appropriate color label. Boundaries can also be measured by presenting two color swatches and asking whether they are the same or different, which is called *discrimination* (see ► [“Color Categorical Perception”](#) for more details). The categorization graphs show a curve that can be classified as one of three types: step, sigmoid, or linear (Fig. 1). The step function is a theoretical ideal not found in empirical data. The discrepancy between the theoretical ideal and obtained data may be due to some meaningless noise in the perceptual system and appears in the data as a sigmoid, even though the actual underlying transition may be a discrete transition. Alternatively, the sigmoid may accurately reflect the boundary: The slope of the sigmoid is indicative of how gradual the transition is between categories. Finally, there could be a linear perception of the stimuli, which would indicate not having categories.

Human experimental data displays sigmoidal categorization boundaries, where stimuli near the boundary are not always reliably categorized into the same category. This area near the boundary is unique, because it represents a place in perceptual space where there is a distortion. This makes between-category distinctions a larger perceptual distance apart, effectively compressing within-category distances between stimuli and expanding between-category distinctions. One account states that categorical distortions are independent from and occur in parallel to continuous hue processing [2]. This issue bears upon whether categorical distortions have an effect on the perception of color or if they are a cognitive phenomenon induced by labeling rather than a warping of perceptual space [3].

D

Dynamics of Color Category Formation and Boundaries, Fig. 1 Panel (a) illustrates a linear or identity function, panel (b) the step function, and panel (c) the sigmoid. A linear function represents sensitivity to continuity and a lack of categorization. The step function is the most extreme categorization, where there is an

instantaneous transition from one category into another category. The sigmoid in panel (c) represents the more gradual transition from one category into another. In each panel, the *x-axis* represents a continuum ranging from category X to category Y, and the *y-axis* represents the probability or activation value for category Y

Further support for the role of labels in the formation of category boundaries comes from comparative work on color perception. Color category boundaries do not arise from pre-cortical processing, as there is no invariant signal coming from opponent process cells or the spectral sensitivities of cones themselves. Thus, it is unlikely that boundaries arise from early low-level visual processes likely to be found in other primates. Baboons do not have color boundaries; rather, they perceive hue linearly, even though their retinal and opponent cell processing are similar to humans ([4]). This evidence supports the role of higher level cortical processing and lends support to the Whorfian hypothesis (also called linguistic relativity). There is also evidence that color boundaries are learned and not innate further emphasizing a strong role for labels [5].

A dynamic view of color boundary formation is well supported by many already existing theories, including linguistic relativity for more detail). This hypothesis acknowledges that the influence of language labels exerts some influence over the perception and formation of boundaries [6]. This influence could modify a boundary in many ways: Two labels could sharpen the boundary between them, making the sigmoidal slope steeper and expanding perceptual distances across the category boundary. One label could make the slope shallower or even linearly perceived (non-categorical). Finally, a label could translate

the boundary, acting as an attractor or repeller for the boundary.

These kinds of dynamics are easily conceptualized as linguistic. However, many other factors could exert an influence on boundaries, such as biology, environment, or context. These alterations of the boundary could also happen at various timescales, on the order of minutes (adaptation; [7]), years (lifespan; [8]), or much longer spans (evolution; [9]). As opposed to thinking of color as something static and invariant, a dynamic view instead emphasizes the role of change and how those occur over time. The typical measurement of boundaries does not reflect influences of context that can alter the boundary [10].

Within a category hues are labeled the same. This could be because they are processed equivalently or because the task forces participants to place the stimuli into one of two categories. If they are processed equivalently, the underlying activation of the category should be all or none: For example, on a given trial, a given hue would be processed as entirely “green.” Alternatively, both color categories may be active to various degrees. For example, the hue would be processed probabilistically as 0.8 “green” and 0.2 “blue.” Over hundreds of milliseconds, the pressure of being required to put the hue in one of two categories would create competition between the two, finally resolving into a discrete answer of either “green” or “blue.” This latter process is called gradient

categorization and was shown to apply to color perception [11].

One study demonstrated gradient categorization in color perception using a computer mouse tracking paradigm [11]. A color categorization task in which participants would begin moving vertically up the screen with a computer mouse and a color from a continuum of green to blue would appear briefly on the screen. The participants would continue moving up the screen and indicate their response by moving over a prototypically blue or green swatch in one of the top

Dynamics of Color Category Formation and Boundaries, Fig. 2 The inputs range from -1 to $+1$ which represent a range of hues to be categorized. The second layer represents the two category options, and the lateral connections between them perform the competition

corners. The trajectories of computer mouse movements show subtle deviations toward the competing category response option – for example, veering toward green when the final response is blue. These deviations reflect the maintenance of continuous hue detail used to help make a discrete, categorical response. The categorical end goal and the gradation in processing coexist in the competition model and parallel human performance.

To demonstrate the maintenance of some form of continuous detail, whether that is in terms of raw hue value or in terms of distance to the category boundary, there must be evidence of a monotonic relation to the category boundary, as measured by some behavioral channel. This kind of signal is not seen in measurements taken only once per trial, as in typical naming tasks. A category boundary of some sort is mathematically guaranteed in a task requiring a decision between one of two items: Thus, within-category subtleties in processing are often neglected by measuring the boundary, which is informative about what is happening near the boundary (e.g., the steepness of the slope indicating the amount of distortion near the boundary).

Dynamics of Color Category Formation and Boundaries, Fig. 3 Competition over time: the two nodes activations are plotted over a number of cycles. You can see the activations begin very similarly, and then gradually one

begins to win, and it rapidly takes the activation away from the other node. This simulation contains a random noise term, which is responsible for the smaller fluctuations in each line, and can produce variability in the final response

Graded categorization can be computationally modeled as competition or even with an evolutionary algorithm emphasizing the role of motor movements [12]. Competition can be implemented with lateral inhibition, meaning that two representations are connected laterally and mutually inhibit one another (Fig. 2). This kind of a network shows gradations in performance during perceptual choices [13]. This network will cycle through the lateral connections, gradually taking the category with the highest activation and increasing its activation by stealing from the other node (Fig. 3). A mechanism like this is hypothesized to underlie the formation of discrete responses, and these gradations in initial activation can be seen in motor responses that are sampled at a very high density [11]. The competition model serves as a mathematical proof that one could accomplish a task such as categorical perception with minimally complex circuitry.

Category boundary formation is a dynamic phenomenon susceptible to context such as labels, objects, and the task being used. The typical color boundary is a relatively steep sigmoidal shape, and the steepness of this slope indicates the degree to which the perceptual or cognitive system has warped the continuous hue space. This could be due to competing labels or prototypes. The dynamic view emphasizes the characterization of these boundaries over many different timescales, and many different areas of color perception address these kinds of dynamic influences (Linguistic relativity, top-down influences, evolution of color categories, etc.) Future directions in this area may look more closely at these variables, and seek to characterize the process in real time, using dense-sampling methods appropriate to the timescale of the phenomenon.

Definition

The possibility that naming colors, either in a single instance or habitually over a lifetime, alters color perception.

Color Perception and Color Communication

When we communicate about the colors of scenes and objects comprising our visual experience, what we see informs our choice of words. A question that has interested many cognitive psychologists is whether the color words we use affect how we see. One view is that naming is for communication and has no effect on how we see or experience the world. In this view, color appearance, and therefore performance on tasks which strictly depend on color appearance, is determined entirely by the visual system and not at all by the language that one speaks. Color vision is informationally encapsulated, its output is automatically produced, and while its output is available for cognitive processes like decision making and speaking, higher cognitive processes cannot alter its process [1]. This can be contrasted with the idea that the very act of naming a color, either in a single instance or habitually over a lifetime, can change one's perceptual experience with the result that colors assigned the same label (i.e., belonging to the same color category) are more difficult to discriminate than colors assigned

different labels (belonging to different color categories).

The two views have persisted in the psychology literature for at least two reasons. First, the empirical evidence has been mixed, with some researchers finding effects of color terms on perceptual or cognitive tasks and others failing to find such effects. Second, when positive evidence of the influence of color naming on color perception has been found, it has often been unclear at what level the effects are manifested. For example, the same experimental results might be interpreted by some researchers as evidence that color terms affect how one sees colors and by other researchers as evidence that color terms affect how one remembers or makes judgments about colors. In this entry, we examine the question of how to design experiments to probe the effects of color terms on color perception and cognition and how to interpret the effects.

The study of categorical effects in color perception has its roots in two historical traditions. The first is the Sapir-Whorf Hypothesis, a concept that originated in anthropology [2]. Whorf and Sapir formulated this hypothesis in different ways in their writing, but researchers have generally taken their view to be something like the way in which experiences are mapped onto words affects the experiences themselves, so that speakers of different languages perceive and conceive of the world differently. A second and related historical tradition is the study of categorical perception [3, 4] and in particular the study of phoneme perception in language. Distinctions between certain phonemes, such as /r/ and /l/, are necessary for speaking some languages, such as English, but not other languages, such as Japanese. Adult English speakers are better at the /r/ versus /l/ discrimination than Japanese speakers (though Japanese speakers are above chance, meaning that the effects are not completely categorical). In phoneme learning, it appears that the learning is primarily a loss rather than a gain; the /r/ and /l/ sounds become more similar as a child learns Japanese rather than more different as a child learns English [5]. Psychologists studying color have similarly asked whether making

color distinctions improves sensitivity to distinguish shades that straddle a category border or worsens one's sensitivity to distinguish shades that fall within a single color category.

No color scientist takes seriously the idea that color perception is as categorical as color naming. It is trivial to find two colors that are both called green that can be distinguished from one another. A more nuanced question is whether colors that are named alike show any degree at all of increased perceptual similarity (or decreased discriminability) compared to colors that are named differently.

Breaking the Circularity: The Logic of Measuring Category Effects

To assess the effects of color categories on perception and cognition, one has to sort out the direction of causation: a pair of colors may belong to different categories because they look very different, rather than looking different because one learns to put them in different categories. In fact, it is certain that this happens; colors that look alike are more likely to belong to the same color category, and language groups across the world tend to assign colors to categories in similar ways, though some differences exist [6]. To know whether there is *also* an effect in the reverse direction, that is, an effect of category on perception or cognition, one needs to have a prediction of how similar the colors should be in the absence of a category effect. Given such a prediction, one could ask the following: are two colors from the same category (Fig. 1a, b) less discriminable (or more similar) than two colors from different categories (Fig. 1b, c), even when the two pairs are identically spaced? That is, are “within-category” trials harder than “between-category” trials? This leads to a potentially circular problem. If the stimulus pairs are chosen such that they are equally spaced, then are they not guaranteed to be equally similar? Or, conversely, if one pair is shown to be more discriminable than the other, does this mean that the color space which placed them at equal distances from one another was flawed?

Effects of Color Terms on Color Perception and Cognition, Fig. 1 Testing effects of color terms on a color task. The *upper* panel shows three stimuli that might be used in an experiment to investigate whether color terms affect a particular task. If the task involves memory, the subject may be instructed to first remember a color (“study”) and then identify the remembered color (“test”). If the incorrect stimulus comes from the same category, the trial is considered “within-category.” If the incorrect stimulus comes from a different category, it is considered a “cross-category” trial. The colors were chosen so that *a* and *b* look *green* and *c* looks *blue*, but the observer may not agree depending on the display and individual differences between observers

This entry summarizes the answer to two questions pertaining to whether and how color naming affects color cognition:

1. How are experiments designed to break the problem of circularity posed above?
2. If the problem of circularity can be broken, then what aspects of color perception and cognition show effects of color names?

Model-Based Approaches

One way to break the circularity problem in studying the effect of color names on color cognition and perception is to compare the results to a null model, meaning a model which does not use color categories as part of its machinery even as it tries to predict them. The choice of color space for a null model is an essential consideration. If the space is designed to reflect perceptual similarity, such as the Munsell color space, then it may already incorporate category effects. And if such a space fails to predict performance on a color judgment task, then it may simply indicate that the space did not perfectly achieve its design goal, rather than something about color categories. Hence, a null model is of limited value for the study of effects of language on color processing if the model is purposely shaped to account for the pattern of human behavior, such as the Munsell system or the CIELab space.

In contrast, a model that sticks more closely to peripheral aspects of color processing can be informative. For example, Brown and colleagues used the MacLeod-Boynton space to predict reaction time in a visual search experiment for an oddball color [7]. The MacLeod-Boynton space represents color stimuli as a linear transform of cone excitations. It contains no information about color names or categories or other properties of color cognition. In the visual search experiments, one color (the target) differed from the other colors (the distractors), and the time to find the target was modeled as a function of the difference between the target and distractors in MacLeod-Boynton space. Trials in which there was a large difference between the targets and distractors in the space were predicted to have a faster reaction time. Some trials were cross-category and some within-category, analogous to the design in Fig. 1. The authors found that the null model provided a good fit to the empirical results, with no systematic deviations for cross-category trials. For this color task, color discrimination time could be explained by a model based only on cone absorptions, and hence there was no evidence that discrimination was affected by color categories. The null model succeeded.

It is important to consider what happens when a null model fails. Suppose, for example, a model predicts that stimuli a and b and stimuli b and c in Fig. 1 are equally discriminable, and yet experiments show that cross-category pairs are discriminated faster or recalled more accurately than within-category pairs. While additional mechanisms or a different model may fit the data better, it does not follow that color categories made the stimuli more discriminable. It may simply be that the model was incorrect or inappropriate for the task.

Equating Color Stimuli but Varying the Subject Population

Another way to break the circularity problem in studying the effect of color names on color cognition and perception is to test identical sets of color stimuli with speakers of languages with differing color terms.

For example, for English speakers there is no common color word that refers to all three stimuli in Fig. 1. Speakers of some languages (sometimes called “grue” languages), however, could refer to all three colors by the same name. An experimenter can therefore avoid the difficulty of perfectly equating differences between the stimulus pairs: for speakers of languages like English that place a boundary between stimuli b and c, the b/c pair should be more different than the a/b pair *relative to* speakers of “grue” languages. The colors are controlled not by the exact localization of colors in a color space but rather by showing exactly the same sets of colors to different groups of observers and seeing if their pattern of responses differs. One of the challenges in such experiments is finding appropriate subject populations. Color naming patterns are quite similar across many languages. Nonetheless, large differences in naming patterns can be found by comparing populations from an industrialized western society such as the UK or the USA with speakers from more remote cultures which have had minimal contact with western societies, such as the Dani and Berinmo of Papua New Guinea or the Himba of Namibia. However, even among modern industrial societies, differences can exist. For example, Russian speakers use different

words for the colors light blue (“goluboy”) and dark blue (“sinij”), while English speakers may refer to both as “blue.”

The results of cross-linguistic studies have not been uniform. Some have found effects of language on a color task, such as a color memory task comparing English speakers with Berinmo speakers [8]. Others have found little to no effect. One reason is that the effects, even when found, tend to be small compared to the shared properties of color processing found in all observers. For example, consider the effect of metamers: two colors with quite different spectral power distributions will be indistinguishable to an observer if the two colors result in the same pattern of cone excitations. This is a very large effect and is quite consistent across observers. A metameric pair for one person is likely to be a metameric pair for another person, or nearly so, unless one of the observers has a color vision deficit. Put another way, three-channel color displays such as television do not need to be tailor-made according to the color naming patterns within a language community. Color metamers do not differ with language because the information lost at the level of cone absorptions cannot be regained. The cross-linguistic differences that have been observed tend to be quite modest in magnitude relative to the much larger effects shared across all observers.

Equating Color Stimuli but Varying the Hemifield: Lateralized Whorf

Rather than testing for an effect of language by holding the stimuli constant and varying the language of the subjects, some experimenters have compared the same speakers but on different sides of visual space. In these experiments, ostensibly the same set of color stimuli are shown on either the left or the right side of a fixation point. The logic of this kind of experiment is that verbal processes are computed primarily in the brain’s left hemisphere, and visual inputs are routed to the contralateral hemisphere, so that stimuli to the left of fixation are processed more in the right hemisphere, and vice versa. The separation by hemisphere is not complete for either vision or language; nevertheless, researchers hypothesized

that if effects of color terms on color tasks were to be found, they would be larger for stimuli presented to the right of fixation than the left of fixation. A number of reports have supported this hypothesis, known as the lateralized Whorf effect [9]. Other reports have failed to confirm the finding, however, and the reasons for the discrepancies have not yet been resolved [7, 10].

Equating Color Stimuli but Varying the Role of Language: Verbal Interference

Another strategy to break the circularity of measuring a category effect is to use the same set of stimuli under different conditions designed to make it easier or harder to use language in the task. For example, a color task can be conducted under conditions in which the subjects' verbal faculties are engaged with a secondary task, such as reading a list of words aloud ("verbal interference"). If a secondary, language-related task reduces a putative category effect, then the problem of circularity is solved for this experiment. There is no need to precisely equate the distances between color pairs; rather, the role of language is implicated because performance changes when the availability of language changes. Experiments have shown that manipulating the availability of language during a color task can reduce the effect of color terms on the task.

The classic experiment of this type was done by Kay and Kempton [11], who compared English speakers to Tarahumara speakers from northern Mexico. The Tarahumara use the word "siydney" to name both green and blue. Subjects from both groups were shown triads of color chips which straddled the blue/green boundary and asked to select the chip which was least similar to the other two. They found that English speakers tended to exaggerate the distance between chips which straddled the boundary, while the Tarahumara did not. This finding is consistent with the idea that the availability of the terms "blue" and "green" influenced the English speakers' decisions about which color chip was the most dissimilar when one of the chips came from a different category. Kay and Kempton proposed that rather than resulting from some difference in color appearance, the English speakers were

relying on the linguistic distinction to make decisions when the perceptual information was insufficient. To test this idea, they repeated the task, but only allowed the subjects to compare two of the chips at a time. The pairs were set up so that the chip in the middle of the color range could be alternately compared with one of the two to either side. This meant that if the middle chip was at a boundary, it would seem bluer than one chip and greener than the other, thus eliminating the usefulness of having a verbal code. Under these conditions, the English speakers showed the same performance as the Tarahumara.

If a category effect goes away when labels become unavailable or not useful, then it is unlikely that the effect is due to color terms affecting early perceptual processes. While such an account is logically possible, it would require color appearance to be altered only during those moments when one is accessing the labels. A more parsimonious explanation is that the *decision* process is affected by language. Verbal labels may be used to help keep track of the various stimuli in an experiment, either over a memory delay or when comparing stimuli spread over space. If, on a particular trial, all the stimuli come from the same verbal category (e.g., they are all blue), then labels are unlikely to help accomplish the task (and might even hinder performance). In contrast, if stimuli in a trial can easily be assigned with different labels (e.g., one blue and one green), then access to the labels may facilitate memory or the comparison process. If a verbal dual task interferes with the ability to label stimuli, even implicitly, then this may eliminate one strategy or source of information for accomplishing the task and hence may change performance. Thus, verbal interference effects are more likely to reflect a role of color terms on decisions, strategy, and memory, rather than perception.

Cognition and Perception: What to Measure

Thus far we have primarily been focused on how to break the problem of circularity when measuring the effect of color terms on color tasks. Here we focus on the tasks themselves. What kinds of

tasks are used to test for the effects of color terms, and what do the results show?

Subjective Judgments

Perhaps the most natural way to ask whether color terms affect color perception is to ask subjects to make direct, overt judgments about color stimuli. For example, one could present subjects with a variety of color samples and ask them to place into groups those that are most similar. Experiments like these have been conducted with observers across languages. Grouping patterns tend to be similar across language groups, but some differences are found consistent with grouping together colors that are given the same name in the language. The difficulty with this type of result is that subjects may choose to group together colors because they have the same name, rather than because they look most alike. Hence, it is difficult to identify whether the effect of color terms is on perception, or on the strategy of how to form groups.

Perceptual Grouping. A more indirect approach can make it less likely that subjects use a naming strategy to make a decision. For example, Webster and Kay took advantage of the tendency of human observers to perceptually group together objects that have a similar color [12]. By arranging disks into two diagonals with an ambiguous central disk, participants could indirectly report perceptual similarity by indicating whether the disks grouped into a line sloping up to the right or up to the left (Fig. 2). The question they then asked was whether the decision to group dots into a triplet was influenced by color categories, specifically whether there was a bias to group the dot with the diagonals when the three came from the same color category, regardless of the proximity in color space. These effects were compared to a null model based on a linear transform of cone excitations, similar to the approach used by Brown and colleagues [7]. The null model did a good job explaining the data, and hence there was no evidence that color categories modulated the task.

Hue Scaling. Interestingly, a different measure of color perception using the same null model did show a significant deviation from the model. This measure is called “hue scaling,” in which subjects view a color sample and rate the perceived amount

Effects of Color Terms on Color Perception and Cognition, Fig. 2 Gestalt grouping configuration used to study the effect of color categories on color appearance [12]

of red, green, blue, and yellow in a stimulus. Compared to a null model, colors that fell on the blue side of the blue/green border were effectively rated as containing more blue than would be expected purely from the model. That is, the results were biased away from the null model in the direction predicted by an effect of color terms on the task.

Subjective judgments are a desirable way to measure perception because they are direct: if one wants to know what something looks like to a subject, then asking for a subjective judgment is a sensible way to find out. On the other hand, because the judgments are subjective (there is no right answer) and there is no time pressure, these tasks are also amenable to strategic decisions that have little to do with perception. For example, when subjects are explicitly asked to rate the amount of blue in a stimulus, the internal mapping from perception to a judgment may be influenced by the fact that the subject knows that the stimulus falls in the category “blue.”

Memory

Memory tasks designed to probe the effect of color terms on perception or cognition often take the form of remembering a color over a delay and then trying to choose between the same stimulus and a second stimulus, where on some trials the second stimulus comes from the same category and sometimes a different category. Memory tasks have sometimes been used in cross-linguistic

studies and sometimes in studies that included dual tasks (verbal interference). Several memory studies have found effects of color category on performance (e.g., [8, 13]). These studies are consistent with the idea that color terms are used as a dual code in memory; if the subject remembers the term in addition to the appearance, then the subject will be more accurate when the memory test includes only one option from the expected color category.

Reaction Time on Suprathreshold Discrimination

In a suprathreshold discrimination task, subjects typically judge which color patch matches a test color. There is only one right answer, and the discrimination is usually well above threshold so that subjects are expected to make the right answer most of the time. The measurement of interest is reaction time, and the typical experimental question is whether reaction time is faster for cross-category trials than within-category trials. In order to avoid the circularity problem, the experimenter can use one of the strategies described above, such as cross-linguistic comparisons, dual tasks, or varying the visual hemifield to which the stimuli are presented. Alternatively or in combination with these strategies, the experimenter can provide a null model to predict the data.

Suprathreshold experiments have had mixed results. Some have reported an effect of color categories on performance and some have not. When an effect of color categories is found in a speeded suprathreshold discrimination task, there are typically two alternative explanations the experimenter is confronted with. The participant may be faster on cross-category trials because stimuli that come from different categories look more different or the participant may be faster on cross-category trials because a decision is easier to make when color labels support the decision. As discussed above, if a verbal dual task eliminates a category effect, then the effect probably is in the decision stage rather than in the percept.

Subjects' experience with the task may also modulate the contribution of color categories on performance. For example, Witzel and Gegenfurtner [14] found that suprathreshold

judgments were facilitated by category differences between stimuli at many name boundaries. These effects were not apparent in a second group of subjects tested on the same stimuli, but who were trained ahead of time on difficult boundary discriminations. The trained group was also faster and more accurate on the suprathreshold task. One interpretation is that categorical labels were not useful in the training phase, and therefore these subjects learned to make the decision without waiting for the support of a categorical label.

Discrimination Thresholds

Threshold discrimination experiments are among the least ambiguous experiments in psychology. If an observer can discriminate two stimuli, then we can be certain that the observer's perceptual system has encoded the two stimuli differently. If the stimuli are indistinguishable (below threshold), then information distinguishing the stimuli was either not encoded or was lost in subsequent processing. If discrimination thresholds were altered by the color terms in one's language, this would provide the most direct evidence that color terms affect perception of colors. Experiments that have compared threshold discrimination among speakers of languages that divide the color spectrum differently have found no effect of color terms [15].

Interpretation and Future Directions

We began with the question of whether the words we use to describe colors affect how we see. A major challenge in addressing this question is sorting out the direction of causality: since similar colors are likely to be given the same name, and dissimilar colors are likely to be given different names, how does one measure whether naming has any effect on how the colors appear? Several methods have been used to address this problem, including the use of null models, cross-linguistic experiments, verbal interference, and hemifield manipulations.

Despite some discrepancies in the literature, some general patterns are emerging. A variety of tasks and experiments have reported effects of

color terms on color cognition in the domains of judgment and decision making and memory. Results are consistent with the idea that color terms can serve as a dual code in conjunction with sensory representations for certain kinds of judgments. Consider the case of speeded discrimination tasks, discussed earlier. In these tasks, there are two sources of information that can inform a decision whether two colors are the same or different. One is a sensory representation and the other is a label. In some situations, for example, when reaction times are slow and the two samples belong to different categories, the labels are useful and may speed reaction times. In other situations, such as two samples having the same color label, or subjects who are trained to respond faster than the labels arise, the categories are not useful and therefore will not contribute to the decision or may even interfere. This kind of explanation – that a dual code explains many effects of color terms on task performance – implies that the effect of color terms is on the perceptual decision-making process, and not on the sensory representations.

In contrast, there is no firm evidence that color appearance or color threshold discrimination is affected by color terms. The pattern of results in this way differs from phoneme discrimination. This may reflect the fact that phonemes have a categorical function: words are combinations of phonemes, and if a phoneme is mis-categorized, then the word may be misheard. In contrast, objects and scenes are not combinations of color categories. There is generally no need to categorize or label a color in order to recognize an object or scene. The fact that we *can* categorize colors by labeling them may have implications for how we remember or reason about colors, but because labeling is not an inherent part of a visual process, perhaps we should not expect it to have a significant effect on visual appearance or discrimination.

In sum, there is a growing body of evidence that color terms affect some tasks involving color cognition, but no strong evidence that color terms affect sensory representations. Put another way, the closer a color task is to language, the more likely it is that it will be affected by the terms in one's language. Hue scaling involves

explicit judgments about color names, and so it is more likely to be affected by color terms. Memory is more likely to involve linguistic codes than perception, and so memory tasks are more likely to show effects of color terms. For any given task, it might not be immediately obvious whether linguistic codes are used. Future work on the topic would benefit from explicitly modeling the psychological processes involved in specific color tasks, in order to better understand how color terms affect the various components of cognition such as memory, decisions, and preferences.

Electrical Control Gear for Lamps

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Definition

Device(s) in the electric lamp circuit of gas discharge and solid-state lamps which limits the lamp current to the required value and ensures that the lamp can be started and once started can be operated stably over a more extended period.

The devices needed are called igniters, ballasts, and, for LEDs, drivers.

Igniters

Most of the gas discharge lamps have such a high internal resistance that they need a voltage peak, higher than the normal operating voltage, to initiate the discharge.

Igniters for Fluorescent Lamps

In most fluorescent lamp circuits, the electrodes are preheated for a few seconds before a high-voltage peak is applied across the lamp to initiate the discharge. Preheating of the electrodes facilitates the emission of electrons. Glow-switch starters are often used for this purpose. However, their harsh peak voltages have an adverse effect on lamp life. Electronic starters with exactly the same functions as the glow-switch starter, but with a better-controlled voltage peak, are used extensively. They always ignite after one ignition pulse, thus eliminating flickering during ignition. Because of the better control of the ignition peak, electrodes suffer less damage, so that lamp life increases.

Igniters for HID Lamps

Ignition of HID lamps is initiated by a high peak voltage without preheating of the lamp electrodes. Igniters for HID lamps are normally started using an electronic igniter that generates a series of high-voltage pulses of the required magnitude (varying for the different lamps between some 200 and 5000 V). The electronic circuit is so designed that these pulses cease after ignition has taken place. Because of differing requirements for ignition voltage, shape of voltage peak, and number of voltage pulses within a certain period, each type of HID lamp (and often also each different wattage) needs its own type of igniter.

Ballasts

If mains voltage is supplied to electrical devices, the current has to be limited; otherwise, it will

keep increasing until the device or circuit in which it is flowing breaks down. In many electrical devices, the internal electrical resistance of the device limits the current. These are devices with a so-called positive-resistance characteristic in which the current is automatically limited to a small range. Incandescent lamps have a positive-resistance characteristic and thus need no separate current-limiting device. Gas discharge lamps have a negative resistance characteristic, meaning that the unlimited current available will increase until the lamp breaks down.

Electromagnetic Ballasts

By introducing an external resistor in the lamp circuit, the current is stabilized. Simple resistors can thus be used as current-limiting ballasts for gas discharge lamps. They do, however, dissipate a lot of power. Instead, inductive coils are used, viz., copper wire wound around an iron core. They have the same effect as a resistor, but at much lower power losses in the ballast. The ballast also ensures that the lamp continues to operate despite the fact that twice during each frequency cycle of the mains voltage (in Europe 50 Hz and in the USA 60 Hz) the current is zero, the lamp is off and thus has to be reignited. An inductive ballast system helps to reduce the time the lamp is “off” during each zero passage of the current. This is because an inductive system shifts the phase between mains voltage and lamp current.

Until the 1980s, all ballasts consisted of inductance type of ballasts also called “electromagnetic ballasts” because of the electric and magnetic fields their coils generate. Since then, more efficient electronic ballasts have been developed.

Electronic Ballasts for Fluorescent Lamps

Electronic ballasts for fluorescent lamps electronically transform the sinusoidal 50 Hz mains frequency into a square-wave voltage of higher frequency, hence their name HF electronic ballasts. The high-frequency voltage lies between 25,000 and 105,000 Hz (viz., 25–105 kHz). HF electronic ballasts work on the same inductive principle as conventional electromagnetic ballasts. At the higher frequencies, much smaller coils with correspondingly smaller losses can be

used than in conventional electromagnetic ballasts. When a fluorescent lamp operates on a frequency higher than some 10 kHz, the efficiency with which the radiation is created increases. The more efficient light production combined with the lower ballast losses means that the system efficacy of fluorescent lamps operated at high-frequency increases by some 20–25% compared to that of the same lamps operated on electromagnetic ballasts.

The electronic ignition function is incorporated in the ballast. With the electronic operation, the exactly required starting voltage pulse can be accurately supplied to the lamp. This minimizes electrode damage and so considerably increases lamp life. Relative to lamps operated on electromagnetic ballasts, lamp life is increased by 30–50%.

Electronic Ballasts for HID Lamps

Electronic ballasts for HID lamps have become available for some types of HID lamps. In contrast with HF electronically operated fluorescent lamps, there is hardly anything to be gained in terms of improved efficiency in the light-creation process by operating HID lamps on an electronic ballast. Nevertheless, energy savings are obtained, because the power losses in electronic HID ballasts are lower. The advantages of electronically operated HID lamps often lie in the better and easier control of certain lamp properties.

Drivers for LEDs

Instant starting is no problem with solid-state lamps, but they are low-voltage rectifiers that allow current to pass in one direction only. This means that the AC mains supply has to be transformed to low voltage and then rectified into a DC supply. Although a solid-state light source has a positive resistance characteristic, the voltage-current dependency is exponential in the area of operation. Small fluctuations in supply voltage, therefore, cause large variations in current that can damage the light source. A simple series resistor in the electrical circuit stabilizes the current to create, in fact, a “constant” current supply.

In practice, only miniature indicator LEDs use such a resistor. Because so much energy is lost in resistor-type drivers, all high-power, high-brightness LEDs employ electronic drivers that provide for the transformation from high voltage to low voltage, for rectification, and for the constant current supply.

Power losses in electronic drivers vary, according to their quality, between something like 10% and 30%, with really poor-quality drivers, as much as 50% of the nominal wattage of the LED itself.

Definition

Lighting to ensure the safety of users and visitors of a building when the normal lighting fails.

Security Lighting Standards

The most important objective of emergency lighting is to ensure the safety of users and visitors of a building when in the case of a calamity the normal lighting fails. Emergency lighting, therefore, uses a power source that is entirely independent of the source supplying the normal lighting. In most countries, the emergency lighting of buildings is regulated in laws. These laws may be aimed at those responsible for the building and building installations or those responsible for the people in the building. In many countries, these laws refer to national or international standards for emergency lighting. Such standards are usually split in, on the one hand, standards for specifying the emergency lighting quality and, on the other hand, for specifying the quality of the products used in the emergency lighting installation. The emphasis here is on the emergency lighting quality specifications.

The International Lighting Commission, CIE, produced in 2007 an ISO/CIE standard that specifies lighting requirements for emergency lighting [1]. Many national and regional standards are based on this standard. The 2013 emergency lighting standard of the European Standardisation Commission, CEN, is an example of such regional standard [2]. This standard has incorporated some clarifications and improvements where inconsistencies existed in the 2007 ISO/CIE standard. Therefore, here the more recent European standard is used as a basis for recommended lighting values.

Emergency lighting levels specified in the next sections are maintained lighting levels and do not take into account indirect light contributions so that the minimum effect of the emergency lighting is not affected by changes in the reflectances of room surfaces, for example, by repainting or redecoration.

Categories of Emergency Lighting

Emergency lighting comprises lighting that facilitates the evacuation of a building in an emergency, as well as standby lighting enabling the continuation of activities of vital importance

Emergency Lighting, Fig. 1 Different categories of emergency lighting with, in italic characters, the objective of lighting

during a power failure (Fig. 1). To facilitate evacuation, persons should be able to orientate themselves in their environment, to locate an escape route which is indicated with discernible signs and safely follow that escape route to the exit. As shown in Fig. 1, escape lighting can be subdivided into escape-route lighting, enabling a safe exit, anti-panic open-area lighting, lighting of points of emphasis such as places with safety equipment, and high-risk task area lighting enabling the shutdown of dangerous processes. Safety signs used for guidance in an emergency should have internal or external lighting that makes them conspicuous and legible from appropriate distances.

Escape-Route Lighting

The emergency plan designated escape routes, marked with safety signs using pictograms and colors, should have lighting that identifies the escape route and enables the safe use of it. For this purpose, the center line of the escape route should have illuminance values at floor level, along each point of the line, of at least 1 lux. For escape routes up to 2 m in width, a band centered around that central line, consisting of at least half

the width of the escape route, must have at all points at least an illuminance of 50% of the illuminance value provided on the central line (Fig. 2, top). Broader escape routes can be treated as a number of 2 m wide strips or as anti-panic open areas.

If the diversity of the lighting, i.e., the difference between the minimum and maximum illuminance values, is too high, the higher illuminance values may affect visibility in the areas with lower values. To restrict this adverse effect, the diversity of the lighting (E_{min}/E_{max}) must be better than 1/40 (Fig. 2, middle).

Disability glare should be limited. The ISO/CIE and CEN standards specify maximum luminous intensities for the zones shown in gray in Fig. 2, bottom. For equal-level floors, the luminous intensities must be limited within the zone 60° to 90° from the downward vertical, whereas for non-level escape routes, such as stairs, the limiting values apply to all angles (see Fig. 2, bottom, again). The luminous intensity limit of 500 cd as shown in Fig. 2 is valid for luminaire mounting heights smaller than 2.5 m. The standards specify larger values for a series of larger mounting heights. The largest intensity tolerated

Emergency Lighting, Fig. 2 Escape-route lighting requirements for routes up to 2 m in width. Top, illuminance levels; middle, illuminance diversity; bottom, zones

in which luminous intensities have to be limited to restrict disability glare. Values based on [2]

in the standards is 5000 cd for mounting heights larger than 4.5 m.

The emergency escape-route lighting must reach 50% of the required illuminance within 5 s and 100% within 60 s. The escape-route lighting should continue to provide lighting for at least 1 h.

Escape lighting should not only make the route itself visible but also the safety signs should be discernible. For this reason, the color-rendering index R_a of the light sources used for the emergency lighting should be at least 40.

Open-area lighting: Open-area lighting is also referred to as anti-panic lighting. The objective, apart from helping to avoid panic, is to facilitate reaching a place from where an escape route can be easily found. The horizontal illuminance at floor level must at least be 0.5 lux, and the

diversity ($E_{\min}/E_{\max}$) should be better than 1/40. Disability glare should be limited just as specified for the escape-route lighting. Also the start-up time, duration, and color-rendering index of the light sources should be the same as for the escape-route lighting.

Points-of-emphasis lighting: Points of emphasis are points where an escape-lighting luminaire has to be placed (less than 2 m from the point). If relevant, such a luminaire can be part of the escape route or anti-panic open-area lighting. The most critical points of emphasis are:

- Exit doors intended for use in an emergency.
- Each flight of stairs or any other change in level.
- Each change of direction and intersection of corridors.

- First-aid posts, call points, and points with escape equipment for the disabled; first-aid boxes and firefighting equipment must have emergency lighting providing a vertical illuminance of at least 5 lux.
- Disabled refugee points.
- Safety signs that are part of the emergency plan.
- Outside the final exit at a place of safety.

High-Risk Task Area Lighting

The objective of this category of emergency lighting is enabling the shutdown of dangerous processes; these may range from short-lasting hazards like operating an electric saw or long-lasting hazards like a metal or glass oven with the danger of hot liquid pouring out. General emergency lighting standards may not cover all potential risks. In the analysis phase of the emergency lighting design process, it should be carefully checked with the responsible person for the processes whether the standard is relevant enough.

Typically, high-risk task areas should at least have an illuminance on the task area of 10% of that required for the task under normal conditions, but not less than 15 lux. The illuminance uniformity, E_{min}/E_{av} , should be better than 0.1.

The lighting must reach 100% of the required illuminance within 5 s unless the process is identified as one requiring a shorter start-up or permitting a longer one. The lighting should continue to provide lighting as long as the risk lasts.

Disability glare should be limited just as specified for the escape-route lighting, and the color-rendering index should also be the same, i.e., at least 40.

Standby Lighting

The objective of standby lighting, also called substitute lighting, is enabling an uninterrupted continuation of activities of vital importance during a power failure. The vital importance can have a safety but also a technical or economical reason. An example where standby lighting is required is the hospital operating theater. The lighting requirements of the standby lighting have to be

discussed with the responsible persons for the activity. The lighting requirements are often the same as the requirements under normal operating conditions.

Emergency Lighting Installation

The emergency lighting installation has its own power supply system, completely separate from the mains power supply of the normal lighting. The system can be centralized or decentralized. In a centralized system, one central power supply unit powers the emergency lighting luminaires. In a decentralized system, the individual emergency lighting luminaires are equipped with a chargeable battery making it self-contained luminaires.

Centralized System

A centralized system uses a set of accumulators or batteries of sufficient power to start and maintain the emergency lighting through an own cabling network. The units are located at a central location appropriately protected against disturbing external influences. A non-break generator can be used to take over from the batteries to extend the period that the emergency lighting stays on. The cabling network has to fulfil stringent requirements, in particular as far as fire protection is concerned. Centralized systems are so-called nonpermanent systems in the sense that they are normally switched on only in an emergency.

The emergency luminaires can be given a double function by powering them from the mains under normal conditions and integrating them in the normal lighting. In an emergency, they continue to receive power, now from the emergency power system. Of course, such integrated luminaires must be of the same type (visually and light-technically) as the other luminaires used under normal conditions. For escape-route lighting, this may be not realistic, but for the open-area lighting, it may be a possibility.

Regular tests to check the proper operation of the emergency system can easily be carried out with central systems.

Decentralized System

In this system, the individual emergency lighting luminaires have an individual power supply in the form of a chargeable battery. The luminaires thus function self-contained or autonomous. The luminaire itself incorporates the functions of power supply, battery charging, mains failure detection, and illumination. The battery is charged under normal conditions by the standard mains power. Self-contained luminaires can be used individually or in groups. Luminaires can be executed as permanent or nonpermanent luminaires. Permanent luminaires provide lighting also under normal conditions. This can, for example, be applicable for the escape-route signalization. In this way, the users of the space can get acquainted, under normal conditions, with the emergency escape routes. At night, they can serve, partly or entirely, as security lighting.

An important advantage of decentralized systems using self-contained luminaires is that the system cannot be affected by faults in the central power supply or cabling network. In the case of a calamity, especially the latter can become a reality. If there is a power defect in only one or a limited number of groups, the self-sustained luminaires in that group or groups respond. Extensions of the emergency system are easily made with a decentralized system. A disadvantage of decentralized systems is that the regular tests of the proper functioning of the system are time-consuming for the maintenance staff and may interrupt normal activities at the location of the luminaire. Self-test emergency luminaires can replace the tests carried out by the maintenance staff. When a defect is detected in the self-test carried out by the luminaire itself, it displays a visual warning.

Definition

Environmental color design involves the use of color in order to configure it as a more beautiful, usable, and informative component of the environment that allows theoretical and practical activities. Color design is a relevant aspect of environmental design, which includes such disciplines and practices as landscape design, urban planning, architecture, interior design, industrial design, engineering, graphic design, textile and fashion design, etc., all of them aimed at a transformation of the natural environment with the purpose of adapting it to human life.

Antal Nemcsics: Deceased.

The Function of Color in Space Experience

Man living in a built environment, the user of a built space, is protected from the tribulations of nature; he utilizes the services of his surroundings and enjoys comfort from these services. In addition to its actual measurable properties required for the physical and biological existence of man, built environment has other qualities too.

Built space acts upon man in several ways: by the proportions, the relationship, and shape of its elements, the order of forms, by surface appearance and colors of the elements, by the relation between space proportions, by the expression of function, by the relation between the expressivity of function and the function proper, and by the shape and color associations expressing function. This effect materializes as an emotional experience of the actual space, and space sensation. Space sensation is an experience about a given space, an accomplishment of one's own personality.

The Function of Color in Space Perception

Space perception is a complex process to which several sensory organs contribute. Among them, visual and auditory stimuli and those arising from motion in space are the most important. All these add up to a space stimulus eliciting the perception of space.

Space stimulus is elicited by measurable and tangible real space, composed of space elements as well as of correlations between shapes and surface appearances, all describable by physical magnitudes. Most of the information about the objective correlations, shapes, and surface appearances of space elements is obtained by reflection, absorption, or transmission of light by the surface of the element that delivers visual stimuli to observers.

Assuming that the surface appearance of space elements is of the same finish, texture, and color, and that the elements are illuminated from the same direction, with the same intensity and

spectral distribution, then due to visual and motional parallaxes, overlapping, line and air perspective, and light-shadow effects, a space perception with a linearity directly proportional to that of the change of the real space is elicited.

Color identity as a condition means that light incident from the surfaces into the eyes has the same wavelength; that is, color sensation is the same throughout, and also, that for the same angle of incidence, the ratio of the quantity of light incident on and reflected by surfaces is the same everywhere, and in the reflected light incident on the eyes, the ratio of complementary radiations, hence saturation, is felt to be the same throughout.

To examine the function of color, let us assume that stimuli arriving into the eyes come from the elements of such an objective space where dimensions, proportions, and relations of the elements do not permit overlapping and the interpretation of line perspective relations; further the onlooker does not move in space, missing the help from laws of motion parallax in space perception. If these conditions are met, and in addition direction, intensity, and spectral energy distribution of light within the space are constant and the former restriction of equal hues, saturations, and lightnesses of surface colors holds, the objective space can be judged only by evaluating the perceived color sensation differences.

Intensity differences of the stimuli emitted by space element surfaces and reaching the eyes permit, first of all, to decide on the spatial position of the light source, then, from hue, saturation, and lightness differences of space element surfaces, on the distance of space elements from the onlooker, hence on the space itself.

It is known by experience that the more remote an object, the more hue component of the color sensation generated by its surface is shifted to hues of shorter wavelengths, its saturation toward achromatic colors, and that its lightness component varies as a function of the two other components and of the position of the light source. This experience helps the space sensation although its significance can really be perceived only if the former condition of color identity is abandoned. In reality, this is always the case. With space elements painted different colors, it cannot be

decided anymore which element is the closer and which is the farther away. Orange and red, even if in reality more distant, are felt to be nearer than blue or green. Saturated colors are felt to be nearer than are unsaturated ones. Very dark surfaces emit very little or no stimuli to the eye, so that these are not sensed, rendering space perception impossible.

The Role of Color in Expressing the Function of Space

Color contributes to space sensation also by expressing the function of space. Function of the built environment is a demand raised to social level. Structural relations in a system composed of man and the elements of his environment are defined by a complex function having three components: utility function, aesthetic function, and informative function. This section explains how color – color stimulus and color perception – contributes to the realization or expression of these functions.

Environment is the scene of human activities, serving human demands. Much of these demands refer to the utility function of environment. Built environment is required to protect from the rigors of weather, to endure dynamic forces generated by human machinery, to protect from such factors as excessive temperature fluctuations, intense noise, and other factors from working processes detrimental to health. A recent requirement is feeling of comfort in one's milieu so as to stimulate the development of mental and physical abilities.

Color has a significant function in meeting these demands. Due to its psychophysical and psychosomatic effects, it may raise blood pressure or change the composition of blood and gastric juices. Color can make one feel healthy or ill. A person in an environment of preferred colors feels better; his/her ambition to work increases. Some colors favor concentration; others cause deconcentration [1].

Just as anything else, built space and all its elements are separable unities of content and form. Environment fulfills its aesthetic function if it expresses its utility function in conformity

with the unity of content and form, where the utility function is the content, while form is expressed by shape and color of environmental elements. Since the content of objects in the environment, let alone in the built environment, is its function, the built space and objects within its content can only be grasped and fully expressed by means of their proper functioning and operation. Practical and spiritual components of the function are interdependent. Even the remark may be risked that aesthetic design of an object or built space is impossible when ignoring its functions. As a conclusion, there are no aesthetic prescriptions of general validity.

In designing color relations for a built environment as a human creation, it is also a question of what importance is attributed to practical functions of the environment for human life in general. Every work and activity is linked to emotions, thoughts, and ideas, therefore every object, tool, or built space demands its share of these mental, emotional, ideological threads, in conformity with its role, significance, and function in one's life. Colors of the built space as elements of form in the couple content and form are made necessary by the sensation of function, giving rise to a harmonious sensation of the indissoluble unity between content and form in human consciousness. Of course, the sight of some color complex may cause aesthetic pleasure, but detached from the content of space, i.e., from its function, this pleasure lacks the effect of complete space experience.

Those who wish to express the message of built space have to know about relations between environmental structures, i.e., about the so-called compositional relationships, in order to be able to create proper relations between forms and color perceptions. These relations comprise color harmonies. Thus, the design of space sensation also exploits color harmonies in this space.

Informative functions of space are features that interpret the functions of the environment and its elements and explain how to use and operate these elements. A significant part of the informative functions of the environment are borne by chromatic information. According to their message, chromatic information may be interpreted either as logic or as aesthetic information. Both kinds of

information are borne by the same elements, but every form of message has its own structure. Their characteristics are determined partly by differences in the visual system, complexity, and structure and partly as psychic differences between their communication content. Information content is transmitted by highlighting, contracting, and grouping some visual symbol elements in the informative surface or space, while omitting others. A color group draws attention when it is clear cut and its structure is easily intelligible.

Chromatic information of a logic nature, i.e., the various standardized color codes, are practical tools that appeal to a logical mind. They transmit messages and serve also to influence observers in their decisions and control their attitudes and behavior.

Aesthetic chromatic information is primarily emotional expression of inner conditions and is expected to have mental and emotional effects by commonly accepted semantics. By their operative and recording functions, visual codes are not only bearers of the meaning of the content of built space and its social concept but also expressions of the approach and culture typical of the creative subject. Chromatic in-built space information necessarily and conveniently takes the form of color harmony relations. This is why it is of prime importance to examine color harmony relations.

The Color Dynamics of Color Theory and Practice of Environmental Planning

Nowadays color dynamics is regarded as a dual activity. One side is the disclosure of man-to-color of complex man-to-colored environment relations and the elaboration of methodologies for the design of colored environment. The other side is the utilization of these findings in environment design practice. These activities involve the collection and systematization of knowledge on relations of man, color, and built space offered by different disciplines as well as to devise and realize research to fill the gaps. This activity has taken momentum worldwide, whereby the science of color dynamics came into being.

Color dynamics as a new science is concerned with the relations between the surface appearance of environment and environmental elements and man living in this environment. It studies the interrelations of color, man, and environment. Thus, color dynamics as a science is a complex of theoretical and practical activities directed toward the disclosure of objective relations between man and colored environment, as well as toward a conscious environment color design.

Rather than a collection of everyday experience, color dynamics is a science. Although it investigates and processes the spontaneous, intuitive transformation of the environment by individuals, it handles its information by scientific methods, applying scientific methods in environment color design. It has been proven both theoretically and practically that it is possible to conduct these activities by exact, scientific methods.

Environment design – including any architectural activity – has increasing access to results of this new science. Its practical application helps the built environment to cope better with its function, to be more beautiful and more sophisticated. It helps humans to expand mental and bodily abilities, to compensate for harmful effects of the overwhelming industrialized environment, to develop an adequate space perception, and to understand spatial relations and correlations between spatial processes. Conscious application of colors is expected to direct and orient man between multiplying and often depressive environmental hazards.

The science of color dynamics has five different but inseparable branches; the achievements of each are interdependent. Knowledge and relations amassed by other sciences are collected and purposefully systematized, and its special research problems are based on this foundation.

The fundamental problem of color dynamics is to find relations between color sensations, to develop an aesthetically uniform color space and a color system fairly approximating to it, and to introduce a new system of color coding suitable for practical color design.

The second group of problems is concerned with man to color relation independent of the

environment. This involves color composition problems in connection with the processes of color vision. Such problems are, for instance, stimulus thresholds and difference thresholds, color adaptation, color constancy, color contrast, color preference, color association, and the psychosomatic effects of color.

The third group of problems includes the complex relation between color, man, and built space, including problems of color and space, color and mass, color and form, color and texture, color and function, color and illumination, offsetting harmful environmental effects by color, and finally the social functions of color.

The fourth group of problems is related to color harmony research, the establishment of color composition relationships for use in practical color design: the determination of levels and parts of the concept of color harmony, of the fundamental and accessory conditions of eliciting color harmony sensations.

The last, fifth, group of problems is the development of the most effective methods of color design, the best way of incorporating the finding of color dynamics into practice. Statements are made exploiting practical observations obtained from realized color designs.

Color environment design activities, as all other design activities, constitute a continuous battle between prevailing conditions, demands of different trends, and artistic intentions. This battle may express itself on many different ways depending on the knowledge base and personality of the designer. Color dynamics has no intent to provide design recipes; rather it shows a method to provide possibility for considering different conditions and enforcing different demands [2].

Color Expression in the Built Environment

Finding a basis for using color as a concept in design is possible through the perceptual experience of color and form. Figure/ground recognition in a visual field is based upon perception. Figure/ground also implies a hierarchical relationship.

Color and form are codependent in built form. This form can be holistic as it relates to an urban environment, or it can be an individual building. Color plays an expressive role in both. In the city, color has the power to create unity in built form by the use of a dominant color in the building materials. This visual unity can be a characteristic of a part, or district, within an urban environment, or it can be a characteristic of the whole. Unity defines a sense of place and gives identity. It also characterizes an urban fabric or background that can define the public spaces and serve as a backdrop for significant figural structures. The architecture of this background is critical to the designer's goal of creating spatial definition and unity in the plan of a city.

Another role for color expression in the built environment is the color choice for individual buildings that become prominent visually in a physical setting. These are defined as figural colors, and they will achieve this visibility through figure/ground contrasts. The atmospheric conditions and the distance from the viewer will also be a determinant in how effective the color choices are in achieving high visibility.

A third tool for color expression in the physical environment is a strategy for defining space not with walls or edges but with a repetitive use of figural color throughout the space. This strategy uses color constellations formed by elements of similar color in the environment that create a spatial matrix when seen as a whole. Constellations can define urban space in two ways: by experiencing these elements of color as a constellation when viewed as a group and through memory when one views a single-color element from a pedestrian view and constructs the whole conceptually.

Background Architecture

In urban contexts, background is that median color/form of the built environment which most conforms to the overall urban fabric and contributes to its visual unity. Background is also the structure or mass that forms and defines the spaces of importance within the city. The color of this background fabric is a component in the overall visual field. The color of building surfaces comprises a large portion of this field, and these colors

Environmental Color Design, Fig. 1 Dark towers as figural color in the central business district, Seattle, Washington

can be a powerful means for defining unity and consistency. A variety of figural form and color can exist as background in a city through repetition of similar elements distributed throughout the urban fabric. In some cities, such as San Francisco, the background is relatively uniform in hue and saturation. Guanajuato, Mexico, however, has many buildings with highly saturated figural colors throughout the city and maintains its visual unity despite these foreground colors. There are two important roles for color/form in this background architecture. The first is the provision of a context for contrast to structures that are figural and highly visible in the city. The second is one of spatial definition. Background architecture becomes the edges and walls that define public spaces such as streets, avenues, civic plazas, and parks, and their organization represents the hierarchies and communal goals inherent in the plan of a city.

Figural Color

Three perceptual experiences of color have direct relationship to questions of architectural color and

form. These are color contrasts that create figure/ground juxtapositions, the spatial effect of color, and the atmospheric color effect. Of these, figure/ground is important conceptually because it represents a hierarchical structure to which expressive values can be assigned. Figural structures in an urban environment are defined by their mass and height, their form, their position or siting within the city, and their color. In an urban context there are colors that make some buildings figural in contrast to their background. Background colors in many modern cities tend toward low blackness ($s = 10\text{--}30$) and low chromaticness ($c = 10\text{--}40$). Building colors that approach maximum whiteness, blackness, or chromaticness will usually be seen as figural in an urban environment [3]. The climate and atmosphere will affect how figural these colors appear. In most weather conditions, white and saturated colors are prominent. Dark colors will tend to be less figural in overcast or humid conditions and appear lighter [4]. Figural color in cities creates visibility for buildings, and as a tectonic tool this visibility can denote status and provide meaning to a civic community (Figs. 1, 2, and 3).

Environmental Color Design, Fig. 2 Saturated *yellow* as figural color on Queen Anne Hill, Seattle, Washington

Color Constellations

In an urban context, there are examples where figural colors and background colors become joined as a means for defining space within the city. In a two-dimensional color field where many colors are visible, color constellations are groups of similar colors recognized as a pattern or cluster. In a three-dimensional color field such as an urban environment, colors that are similar in hue and saturation can also be perceived as a cluster of repetitive color elements and form color constellations [5]. The area within this array of similar colors can be designated as an urban space, defined not by edges or walls but by a repetitive matrix of similar colors. An example would be the Parc la Villette in Paris [6], where large red architectural sculptures are placed on a grid throughout the precinct of the park. From an aerial perspective, the spatial matrix formed by these red structures is apparent. From a pedestrian viewpoint, only a few of the structures are visible at any one time, although a memory of the precinct as a

whole initiated by the individual red sculptures is always present.

Many city maps are organized by color sections to show important landmarks and institutions, shopping/retail districts, public open spaces, nightlife areas, etc. Many of these nodes and districts are repetitive and dispersed throughout the city. The map represents patterns of color clusters, like a constellation, and a large amount of information about the organization of the parts of the city is made visually accessible and comprehensible. Color in the physical environment has the potential for providing the same visual comprehension. Many cities have zoning in these districts that specify heights of buildings, density, signage and lighting, etc. that help in achieving the goal of comprehensibility from a pedestrian's view of the city, but color is rarely a consideration. One example, however, is in Washington, D.C., where the important governmental and institutional buildings are white with the background architecture in darker hues. These important buildings and

Environmental Color Design, Fig. 3 *White* as figural color, denoting status, Schiers, Switzerland

Environmental Color Design, Fig. 4 Color constellation at Parc La Villette, Paris, France

landmarks form a constellation of white figural structures located in the vicinity of the Mall in the center of the city. As in Parc La Villette, the view of

any of the white buildings recreates an image of the group of figural buildings around the Mall, and any white building near the area becomes a conceptual

part of this collection of significant structures (Fig. 4).

Definition

It is evident that color vision evolved to inform organisms about their environment and thus must be shaped by the environment the organism is in. The color properties of the world are a potent factor affecting not only the basic mechanisms of color vision within a species but also how they are calibrated and fine-tuned within the individual. As a result, many aspects of the physiology of color coding and the phenomenology of color experience can be predicted by looking outside the observer – to analyze the signals available in the color environment. The following provides a number of specific examples of how knowledge of the color characteristics of the environment has helped to account for some of the known properties of our color vision.

Environmental Signals and the Evolution of Color Vision

A central principle in understanding the design of sensory systems has been coding efficiency – or how to transmit the most information about the stimulus using the least resources. The assumption that vision maximizes coding efficiency provides a powerful link between the properties of the stimulus and the properties of the observer [1] and has led to a surprising number of insights about the early stages of color vision and how they are optimized for the color characteristics of the environment. For example, natural color spectra (of both illuminants and surfaces) typically vary gradually with wavelength and can be represented and discriminated based on a small number of spectral samples [2]. This may in part be why color vision is typically low dimensional (e.g., based on three classes of photoreceptors in trichromatic observers). The fact that spectra can be represented by a small number of dimensions has also been a central insight into understanding the capacity and limits of color constancy (e.g., the ability to perceive that the color of a surface has not changed even when the light falling on it has).

Scenes are composed of collections of many spectra, and these color distributions have

characteristic properties. For example, most luminances and chromaticities tend to be near the average, or gray. This property has been used to predict how neurons respond to different intensity or color levels in the image. To code these efficiently, responses should change most rapidly near gray, where signals are more frequent and thus require better discrimination, and asymptote at the extremes (e.g., highly saturated colors), where signals are rare. Thus the color statistics of images can directly account for the sigmoidal response functions of visual neurons and for the fact that we are best at discriminating small color differences near gray [3].

Color vision requires comparing the differences between the responses of receptors with different spectral sensitivities. Because the sensitivities are broad and overlapping, and because as noted spectra vary gradually, the signals within the different cone classes are highly correlated. This redundancy can be removed by recoding the cone signals into “luminance” mechanisms (e.g., in cells that receive excitatory inputs from different cones and thus sum their inputs to represent luminance) and “chromatic” mechanisms (e.g., in cells that instead receive excitatory inputs from one cone type and inhibition from another, so that the response depends on the difference or ratio of the cones’ signals). Thus redundancy reduction provides a rationale for how the cone signals are reorganized in cells in the retina. Finally, the overlap in the cone sensitivities also means that the differences between the cones (which convey color) are many times smaller than the absolute responses (which convey luminance). If our vision depended on these raw cone signals, then the world would vary much more in brightness than in color. However, a further prediction from coding efficiency is that each channel uses its fully dynamic range to code the range of available signals [3]. As a consequence we are much more sensitive to chromatic differences than luminance differences (when equated for cone contrasts), and the range of brightness and color in the world appears perceptually balanced.

The preceding examples illustrate how studies of the color environment have provided insights into general properties of the mechanisms of color

vision. For many species the environment also holds special color signals that are important to detect, because they signal food or mates, and these signals have given rise to more specialized adaptations. For example, most mammals are dichromats, yet humans and other old-world primates evolved a third class of photoreceptor through an evolutionarily recent duplication of the gene coding their longer-wave photopigment. The extra dimension of color afforded by their trichromacy has been shown to be well tuned for detecting ripe fruit among foliage and also for judging the subtle variations in skin tones that signal the health and emotional state of conspecifics [4].

Color Appearance and the Color Environment

Conventional models of color appearance hold that the signals from the three classes of cones are recombined to form three perceptual channels that signal red vs. green, blue vs. yellow, and bright vs. dark. A central issue in color science is how these perceptual dimensions are encoded by neurons of the visual pathway and why particular hue directions are special. Here again the color characteristics of the environment are thought to play a central role.

According to the standard color-opponent model, any stimulus is represented by how it differs from gray (e.g., lighter vs. darker or redder vs. greener). But what establishes gray? The spectral sensitivity of the observer varies in capricious ways depending on factors such as the level of screening pigments or the relative numbers of the different types of cone receptors and thus must be adjusted to match “gray” in the environment. This gray likely corresponds to the average spectral stimulus the observer has been exposed to. Normalizing color responses for this average probably happens at many levels of the visual pathway and at many timescales. For example, there is increasing evidence for distinct processes of short-term and long-term adaptation to color at multiple stages of visual processing [5]. Color adaptation initially arises in the photoreceptors,

which rapidly adjust to changes in the average color or brightness of the scene (e.g., becoming more or less sensitive when the light levels get lower or higher, respectively). These sensitivity changes rescale their relative responses so that the current average color tends toward gray, an adjustment known as von Kries adaptation, and this is thought to be an important initial component in color constancy (since it tends to remove or discount changes in the average color of the scene introduced by changes in the illuminant). Similarly, opponent channels must be calibrated so that the opposing cone inputs are weighted so that their null points (e.g., where the signal is neither red nor green) correspond to a neutral gray. Sensory adaptation thus plays a critical role in calibrating color vision so that it is correctly adjusted to match the observer's environment. (Importantly, these adaptive responses are not unique to color, but probably influence all aspects of perception [6].)

Supporting this, many lines of evidence show that the stimulus that appears gray depends very little on the observer's actual sensitivity to wavelength. For example, individuals vary widely in the density of the lens pigment, which also steadily builds up with age. This pigment selectively absorbs light at shorter wavelengths, and thus the light reaching the retina of an older observer will have a different spectrum from a typical young observer. Despite this, the physical stimulus that appears white remains constant across the lifespan, because color mechanisms are continuously recalibrated so that they are adjusted to the average spectrum [7]. Receptors in the fovea at the center of vision are also selectively screened by a second inert pigment known as macular pigment, which further filters light at short wavelengths. Thus the fovea and surrounding periphery receive very different stimulation on average. Yet the physical stimulus that looks white again remains largely constant across the visual field, suggesting that each part of the eye can locally adapt to set the achromatic point. Patients undergoing cataract surgery provide a natural experiment for observing these adaptation processes. Cataracts represent an extreme form of lens brunescence, blocking much of the short-

wavelength light. Yet the stimulus that appears white is within the normal range for many patients. When the cataract is replaced with a clear lens, the sudden increase in short wavelengths causes the world to appear too blue. However, achromatic settings almost immediately begin to renormalize and continue to slowly drift back to their prior levels over a period that may last for months [8].

Analogous arguments have been advanced to account for the special nature of red-green and blue-yellow as the primary dimensions of color appearance. As noted above, red may be special because it signals ripe fruit or blood. For blue and yellow, a number of studies have pointed out that these hues fall close to the daylight locus (e.g., variations between the sky and direct sunlight), and thus the tuning of the blue-yellow axis is matched to a dominant source of variation in the color environment [9]. In fact, this idea has been taken further to suggest that the special perceptual nature of some hues lies entirely in the environment. In opponent theory, blue and yellow (and red and green) are pure or unique hues because they arise from the pure isolated responses within the blue-yellow or red-green channels. However, a problem for this theory is that neurons with the chromatic tuning predicted by these sensations (e.g., that respond only to pure blue-yellow signals) have yet to be discovered. This has suggested the possibility that observers may learn to perceive the unique hues as special because they are special in the environment and not because they correspond to a unique pattern of activity within the neurons coding color. The number of basic color terms (color words that have high agreement and do not refer to specific objects) and the locations in color space that they denote have also been predicted from analyses of how colors are clustered in images. By this account, red spectra tend to form a distinct cluster of signals, and this salient cluster may be why a prevalent color term for red arose in many of the world's languages. More recent analyses of scene statistics have found that objects (at least as defined by image databases) tend to be warm colors while backgrounds tend to be cool colors, and these differences may also

predict the emergence of different linguistic color categories [10].

Regardless of their neural basis, it is clear that like gray, the unique hues are not strongly tied to the specific spectral sensitivity of the observer. The wavelength that appears pure yellow shows little dependence on the relative numbers of long- and medium-wavelength-sensitive cones, even though these can vary over an enormous range of ratios. Similarly, the wavelengths chosen as representing unique hues cannot be predicted from individual differences in lens or macular pigment density and like gray show little effect of the observer's age. These results could again suggest that the hues are set more by the environment. However, it is important to note that the stimuli perceived as unique hues also vary widely across observers and thus cannot be tightly bound to pronounced and stable properties of the world [11]. Indeed, it remains debated to what extent and in what ways color appearance and color naming reflect properties of the observer, the physical environment, or the cultural environment.

A further potential tie of blue and yellow to the environment is that, in a number of tasks, observers appear less sensitive to this color axis. For example, when individuals adjust a stimulus to appear white, they are much more tolerant of blue-yellow variations than red-green variations, and differences in the achromatic settings between observers also exhibit greater variance in blue and yellow. Similarly, color discrimination thresholds are (in some but not all cases) higher for blue and yellow compared to the sensitivity for other chromatic axes. At suprathreshold, blue-yellow variations can have lower effective contrast (e.g., in a color search task), are rated as lower in visual discomfort (which correlates with perceived contrast), and have recently been found to induce weaker cortical responses as measured by functional MRI. One potential explanation for this bias against blue-yellow is that the world itself has a bias toward more blue and yellow. In particular, in many natural outdoor scenes, the variance in chromaticity is higher along bluish-yellowish axes [12]. The visual system adapts not only to the

Environmental Influences on Color Vision, Fig. 1 Uniform color systems and natural image statistics. *Left:* Munsell colors plotted within a color space defined by the two color-opponent axes coded by the retinal: long-versus medium-wavelength cone signals (0–180 deg axis) and short versus medium and long cone signals (90–270 deg axis). Sets of points with the same shading represent contours of constant chroma. These are elongated in the bluish-yellowish direction, consistent with weaker

sensitivity to these hue directions. *Right:* color distribution characteristic of natural outdoor scenes plotted in the same space. The scenes have a blue-yellow bias corresponding to the sky and earth. Note that the scaling is chosen to equate sensitivity to each axis, and this roughly matches the range of color along either axis. The weaker sensitivity to blue and yellow may be an adaptation to the greater blue-yellow variance in environmental color

average color in the stimulus but also to the range or contrast. Adaptation to the higher blue-yellow contrasts in typical outdoor scenes may thus leave us less sensitive to these hues. Notably, this bias is also built into the structure of perceptually uniform color spaces (Fig. 1). Color order systems like the Munsell system or spaces like the CIE uniform chromaticity diagram are also stretched along bluish-yellowish axes (though these tend to be closer to an orange-cyan axis). Not surprisingly then, uniform spaces may mirror the structure of the color distributions we are adapted to and in

turn might hold clues to the particular color environment we are calibrated for. Recently for example, a new uniform color metric was proposed based on environmental color statistics and how these should be optimally encoded, and this theoretically derived space approximates color similarities about as well as conventional spaces based instead on purely empirical measures of color discrimination [13].

Finally, environmental factors have also been postulated as the source of perceptual differences between blue and yellow. These differences were

Environmental Influences on Color Vision, Fig. 2 Simulations of how the world might appear to observers adapted to different environments. *Top*: images of the same setting in wet (*left*) or dry (*right*) seasons. *Bottom*: the same images with the colors adjusted to simulate the effects of visual adaptation to the average color and to the range of colors in the different settings. Note this

shifts the average color toward gray and tends to highlight the more novel colors in the environment (Reproduced with permission from Juricevic, I. and Webster, M.A. (2009). Variations in normal color vision. V. Simulations of adaptation to natural color environments. *Visual Neuroscience* 26, 133–145)

brought to the fore by the image of #thedress which different observers perceived as blue-black or white-gold, with the explanation that the differences reflected whether the dress was perceived to be in direct light or shadow. Shadows are more likely to be blue and observers tend to discount the blue in shadows and objects and show greater color constancy for blue variations in lighting [14].

Variations in the Color Environment

Clearly, the world is not stationary in its color characteristics and can instead vary widely from one location to the next or in the same place over time as the lighting or seasons change [15]. If observers are adapted to the colors they are immersed in, then we should expect variations in the properties of their color vision as we go from forest to desert or from summer to winter (Fig. 2). The effects of such environmental changes have not been widely studied, but there are telling signs that they occur. For example, recent studies have pointed to seasonal variations in color mechanisms, from photopigment opsin expression to color appearance to color preferences. Variations in visual sensitivity have also been postulated to reflect differences across environments in exposure to the phototoxic effects of sunlight.

A further important source of environmental variation is the artificial visual worlds that humans increasingly inhabit because of culture and technology. As a result the visual diet of an individual can vary in large and idiosyncratic ways depending on their interests and professions. This could in turn lead to very different color percepts. Neitz et al. exposed subjects for several hours at a time to “red” or “green” worlds by altering their room lighting or by having the subjects wear tinted contacts [16]. This led to persistent changes in the wavelength that appeared unique yellow, consistent with a long-term renormalization in color vision. New lighting technology also alters the gamut of colors, and it remains to be seen how and in what ways color vision will adapt to these environmental changes

[17]. However, to the extent that we understand the processes of adaptation, and can estimate the color distributions that observers are exposed to, it may be possible to predict how a color environment will look to someone adapted to it. These simulations can help reveal very long-term consequences of different color environments for perception, and the extent to which individuals living in different environments might have different or similar color experiences [18].

Materiality, luxury, hue, saturation, brightness, intensity linguistically expressed in ancient languages; Problems of the earliest language development in the domain of color; Understanding perception and expression of color in ancient languages

Definition

Conceptual issues related to perception and expression in color categorization, relevant to understanding the impact of ancient thought on the development of abstraction.

Introduction

For Grand-Clément (in [1]) “The ancient Greeks considered golden the best color in the realm of metals and purple as the best color for textiles.” In Greek, *porphúreos*, modern “purple” was an expensive red dye, associated with royalty and divinity, and the sea, and she therefore suggests that ancient Greek expressions of color relied on

economic as well as symbolic values [expressed using] substances [, with] gold and purple [being prominent examples,...] substances could be endowed with specific values and highly esteemed [...] we have to keep in mind that the ancient Greek perception of colors differs from that of the modern viewer: the Greeks [...] paid more attention to brightness and vividness than hues. Moreover, they perceived colors not as abstract categories but rather as visual qualities of objects and substances. This conception of color, deeply rooted in the material world can be observed in the terminology, since adjectives such as *khruuseos* [= *xrúseos*, “golden”], *argureos* [“silver, silver-plated”], *khalkos* [= *xálkeos*, “bronze, brazen”] indicated both the

physical matter and the color of an object. Thus, the first question should be: what were the colors of gold and purple from the Greek perspective?

She is largely correct, but, inadvertently abbreviates and distorts the larger picture. On the one hand, (a) the texts and art offer only the expression and not the perception. On the other, as she starts with Greek material, she fails to stress (b) that both “gold” and “purple” are loan-words in Greek, and thus also neglects (c) the Near Eastern influences that began the conceptual appreciation of color, without abstraction. The Near Eastern use of the names of stones and metals to designate artificial imitations began a tradition leading to the designation of hues. Greek developments are highly significant, but merely a segment of the era of continuous interaction, during which loan-words acted as cognitive levers, lifting meaning.

It was a long era in terms of individual human experience, lasting around five millennia – but insignificant in terms of the biological cognitive capacities of the modern human mind, which probably go back 300,000 years or so. The beginning of abstract color terminology was a cognitive process taking place relatively rapidly in relatively recent times, relying on materials. By the end of the fourth millennium BC, the Egyptian and Mesopotamian elites had become accustomed to the shiny, malleable metals gold and silver along with exotic hard pure lapis lazuli and carnelian. Ultimately, it was from this encounter that conceptual yellow, white, dark blue and deep red eventually emerged, but it was a long process, so that even among the Greeks – thousands of years later – conceptions of color still involved luxury, hue, intensity, brightness, hardness, purity and form (see also Encyclopedia of Color Science and Technology entries on ► [“Materials and the Origins of Abstract Color Naming”](#) and ► [“Ancient Color Terminology”](#)).

“Purity” itself was probably conceptually, linguistically and culturally defined for the first time in this era through refined, pure, “white” silver in Mesopotamia. By the second millennium BC, this approach led to multiple “reds” and “blues”; the high priced precious metals and stones having embodied and enhanced the understanding of

purity and truth expressed through color during the third millennium BC, the formative period for Bronze Age thought.

In (i) the evolution of color expression and perception, the Classical Greeks (in contrast to the Homeric Greeks!) were far closer to a modern understanding of color than the Egyptians and Mesopotamians millennia earlier, as (ii) loan-words (e.g., Greek *xrusós* for gold and *kuáneos* for “blue” were related to the Akkadian *hurāšum* and *uqnû* respectively), and (iii) foreign concepts – silver paved the way for the Mesopotamian invention of the concept of “purity” in “white” which spread across the Old World. Extraordinary is that the range of meaning in the Greek terms *argēeis* (derived from silver) and *leukós* (abstract white) are virtually identical in “shining,” etc., with *leukós* (sic) alone also meaning “pure”; this allowed complex abstract color concepts to develop figurative meanings.

Grand-Clément says that “Aphrodite, the goddess of erotic desire and sexual attraction, was “golden” (*khruśeē*) [= *xruśeē*; and like the irresistible attraction of gold itself,] her radiance was so powerful and extreme that no one – human or divine – could escape her seductive power”; the same powers were attributed to Mesopotamian Inanna/Ishtar and Egyptian Hathor – but only Hathor was the “woman’s gold.” (Gold was a late comer in the Mesoamerican world, yet Mayan and Aztec “yellow” is also associated with “want,” “desire,” and “mature” [3]).

Ereshkigal (the Mesopotamian Queen of the Netherworld) lives in chambers of lapis lazuli, but the apartments of her Greek counterpart Persephone are “blue” or “dark” [4] – using the Greek color term *kuáneos*, derived from the Akkadian designation of lapis lazuli *uqnû* (cf. Fig. 1). But the Greeks knew only the color concept, and the Mesopotamians only the material.

Yet Gladstone [5] concluded that the Homeric Greeks could not see blue – being at a lower stage of human evolution (anticipating Darwin’s *Origins of Species*, published the following year). Today, this is biological nonsense: visual perception of color has not changed in the last 300,000 years. But the difficulty of recognizing blue and green in Ancient Greek linguistic

Evolution of Color Expression, Fig. 1 Inlaid gaming board (96.5 × 55.3 cm) – of silver, ivory, gold, rock crystal, faience, ground glass paste – from Knossos, Crete, ca. mid-second millennium BC [2]. Note both yellow = gold and contrast of light and dark blue; Evans himself [2] uses the word “kyanos” (= *kíanos*) for the

cobalt blue glass paste (of Egyptian origin) used to make the dark blue color (*kuáneos*) imitating lapis lazuli. Craftsmen were handling the materials for the benefit of the elite who became accustomed to color being associated with exotic beautiful things – and this influenced the poets

expression remains – and differs from the concrete appreciation of blue already a millennium before Classical Greek (Figs. 1 and 2). Abstraction in language arrived as a cognitive consequence of what was begun by human contact with the esteemed materials [9, 10]. Blue lost out to purple, as Greek purple was linked to expensive dye while Greek blue was linked to cheaper glass (and not the real lapis lazuli).

The Evolution of the Linguistic Division of the Spectrum

Empirically, first millennium BC Greek and Chinese terminology is not that different from second and third millennium BC Sumerian, Egyptian, and Akkadian. Conceptually, however, in the first millennium BC, both Greek and Chinese conceived of color differently, with a tendency to increasing adjectival abstraction, but decreasing clarity about hue.

The earliest use of red ocher by modern humans dates back more than 100,000 years.

Along with black soot, red and yellow ocher set the limit on color in the Upper Paleolithic cave paintings ca. 35,000 years ago (Moutsiou in [11]). Green and blue are absent until tens of thousands of years later. Green stones obtained prominence beginning approximately 13,000 years ago (Bar-Yosef Mayer in [11]). Red carnelian, black obsidian, blue lapis lazuli, white limestone, blue-green turquoise, jade, gold, and silver gradually and progressively become prominent during the following millennia: all present by the fourth millennium when writing was invented. Until the first millennium BC, color designations remained limited, employing materials as proxies.

Grasping the transformation is difficult, but recognizable. The later Chinese word for “red” *hóng*, had a (possibly linguistically related) homonym meaning “rainbow.” For the Chinese, the rainbow is associated with the celestial brightly colored dragon [12]. The second millennium BC Akkadian understanding of the rainbow (*tirana*) was associated with the form of the weapon

Evolution of Color Expression, Fig. 2 Restored interpretation of so-called “Partridge Frieze” (detail, approximately 15×40 cm) at Knossos, Crete, mid-second millennium BC [6]. The craftsmen were not only handling precious materials characterized by color, but also deliberately creating paints to depict the world – and using color

as the only means available in flat art. Note distinction of different blues and reds, browns (perhaps slightly less than a millennium before Homer). For technical aspects of painting as a means of expression in Antiquity, cf., e.g., [7, 8]

(^{gis}*tir*) – and the same applies to the Egyptian *pdj.t*, designating both weapon and meteorological phenomenon – but not color. This distinction may identify the moment – after the middle of the first millennium BC – when abstract colors appeared in human language and thought. Visible in the Chinese language, it was appearing in Greek thought; the Ancient Near East never reached this level. Significantly, the Aztecs had a completely detailed chromatic understanding of the rainbow (Dupey-García in [1]) – and this seems to build on Greek and Chinese conceptual developments.

The sequence was not built on adding additional abstract words for additional perceived colors, but rather one whereby individual parts of the spectrum were split in accord with materials before adding further abstract color terms – and the difficulties proved insurmountable in ancient Near Eastern thought. Abstraction accelerated when the Greeks and Chinese overcame the Ancient Near Eastern system of exhaustive lists as a means of classifying knowledge, reducing the world to handful of “elements” or “phases,” including colors (Bogushevskaya, Warburton in [1]).

At the moment, there are four dominant theoretical approaches to understanding the emergence of color vocabulary in the earliest

languages. Consciously or unconsciously, many authors – and especially those working on Maya [3] – maintain the framework of the Berlin & Kay Theory. While relying on materiality, Maya seems to build on developments in the Greek and Chinese worlds – leading to a chromatic paradigm roughly compatible with the Berlin & Kay Theory (for which support from MacLaury’s Mesoamerican color survey was fundamental). The recent history of color may be compatible with the Berlin & Kay approach – but accounts neither for origins nor does it reflect the original acquisition sequence.

Since before Berlin & Kay, working with Egyptian and earlier theoretical models, Schenkel (in [11, 13, 14]) started with hue oppositions, but has concentrated on abstract words, defined by (a) verbal (rather than adjectival) categories, demonstrating (b) that a word for “grue” never appeared in Egyptian, as the focus of the relevant word was in green, identifying (c) a failure of historical salience for “white,” and revealing (d) that the fifth color term in Egyptian was a second “red” (rather than a “yellow”). Although superficially similar, Schenkel’s theoretically and empirically founded theoretical system differs fundamentally from Berlin & Kay, while more restricted (but dealing with the most ancient continuous language dataset available).

Working on a different theoretical basis with Akkadian, Thavapalan [15] follows current linguistic and anthropological trends stressing luminosity and saturation more than hue in the formation of the earliest color categories. However, the terminology she identifies demonstrates that materials (stones, glass, metals, dyes, etc.) were decisive for the lexical expression of color.

Working exclusively with developments in ancient color usage, Warburton (in [1, 7, 9, 11, 16]) stresses the importance of (a) the language-based evidence of the precious materials (strong hues in rare hard materials) for color in (b) providing the basis for the emergence of the earliest advanced categorization of color, (c1) enabling the subsequent course of the development of color terminology through loan words, and (c2) guiding the use of the names of the minerals for the artificial products (e.g., lapis lazuli for glass, turquoise for faience), with hue and material going together: material was the foundation whereby abstract terminology was established in the course of recent millennia – and the “materiality” approach is gaining traction (contributions in [1, 11]).

Warburton concurs with Schenkel that the possibilities of the terms for precious materials were not exploited in the Bronze Age so that real abstraction came later in Greece and China. Thavapalan stresses saturation and brightness, but both Thavapalan and Warburton recognize the key role of materials as decisive in the expression of color in the earliest documented languages, and they thus move further along the spectrum than Schenkel who sees a preliminary level of abstraction necessarily excluding “blue” and “yellow.” “Materiality” is gradually becoming the dominant approach to understanding the origins of color expression in language, but for Schenkel (in [11]), this remains otherworldly.

Further Complications for Applying Modern Standards to Ancient Materials

Plato considered terms for “bright,” “brilliant” (e.g., *lamprón*, *stilbon*) to designate colors [17], i.e., identifying “colors” where modern approaches seek hues, with “brightness” an attribute. Ancient Chinese also already had homonyms (e.g., *mìng*), which meant each individually implied some nuance of “brightness” – with “dark” another problem.

The Pre-Greek color terminology was more complicated; e.g., the ancient Egyptian word *ṯn.t* for “faience” also meant “dazzling,” but probably originated in a designation for a type of pale green natural glass (Corcoran, Warburton in [1]). Words like English “black” and “white” are different from “light,” “shining,” “gleaming,” “sparkling,” “dark,” and “gloomy,” respectively, as the latter glosses appear to not have category foci. (See also Encyclopedia of Color Science and Technology entries on ► [“Ancient Color Terminology”](#) and ► [“Materials and the Origins of Abstract Color Naming”](#)).

This is a major obstacle to the application of the Berlin & Kay theory as it implicitly suggests that “dark”/“black” and “bright”/“white” are the same – whereas they are not: artistically (like the Minoans, Fig. 3), the Egyptians went to great lengths to achieve pure blacks and whites in their art (e.g., Warburton in [7]; also Blom-Böer in [11]) – and these were conceptually salient, even if the range of hue categories incorporated into any given word could be broad in the eyes of observers like Schenkel (in [11]).

In early languages the word for a generic “red” may have served as a synonym for “colorful” or “colored.” Peculiarly, the – very late! – Aztec *tlalpalli* (“red”) played a similar role (Dupey-García in [1]). While the color typically labeled “red” in modern English language usage was among the earliest distinguished in art and written artifacts, the concept of a category of a single “red” as a distinct linguistic unit was not dominant in the second and third millennia BC: “red” was distributed among several different words in various languages.

Although often considered “abstract,” the adjectives for colors in Sumerian were never

Evolution of Color Expression, Fig. 3 Restored interpretation of a Mycenaean dagger (detail of blade L: 20 cm) from Greece, mid-second millennium BC [18]. It is Minoan craftsmanship. The bronze blade has been treated so as to accommodate a band of niello plating to form the

shiny black background surface, into which copper, “polished silver,” and “pale gold” inlays were set. The effect of the brightness is due to the pure black background from which the copper, silver and gold shine forth. Pure bright colors were the goal

attached to the *NAM* abstract determinative (in contrast to Chinese where the *sè* radical is added today). Given the difficulties of understanding adjectives in Egyptian, Schenkel used verbs, i.e., *ḥdj* “to be white,” *km* “to be black,” *dšr* “to be red,” and *wādj* “to be green”; although verbs, they served as adjectives; the noun-based *xsbḏjy* “lapis lazuli-like” “dark blue” was a metaphor, simile, or adjective; likewise *mḥkātj* “turquoise-like” for “light blue” or “light-green,” and *nbwj* for “gold,” “golden.” Following Schenkel, the adjectival aspect was introduced through the precious materials.

Early on, loan-words were crucial, as Akkadian *uqnū* and Egyptian *xsbḏj* for “lapis lazuli” or “dark blue” are two different loanwords for an imported material, borrowed from other unknown languages. Other terms shared in different languages named materials but not “abstractions.”

Detailed Linguistic Issues in the Debate About the Significance of Ancient Color Naming

Berlin & Kay’s theory pre-supposed a teleological, universalist, evolutionary convergence in the modern linguistic partition of the spectrum with languages progressively adding additional abstract terms. Baines’s [19] application of the

Berlin & Kay sequence to the earliest languages has been recognized to have failed (e.g., [16], Corcoran in [1]); the empirical support for the acquisition sequence is missing; lack of salience and the importance of loan words throw further doubt on its overall validity. (See also Encyclopedia of Color Science and Technology entry on ► “Berlin and Kay Theory”).

Black and White, Dark and Light

Significantly, a word for “darkness” shared in Sumerian (*gege*, *kuku*) and Egyptian (*kk.w*) means that the word was of great antiquity, since it fed into two distinct language families – or the Sumerian influenced the Egyptian as an early loan word. Yet these glosses for “darkness” were used only in Sumerian to influence “black,” but not in Egyptian where the origin of “black” lay elsewhere (Egyptian *km* for “black” may be related to soot). The original and later Chinese terms for “black” (*xuán*, *hēi*) did mean “dark” – but the Chinese term for white *bái* did not serve as a major designation for “bright” or “clear” (more *míng* and *qīng*). According to the Berlin & Kay framework, there is an implied assumption that “dark” & “black” and “bright & white” can be equated (implying color words which are not necessarily present).

Another peculiarity is clear evidence, in both earlier Greek and earlier Egyptian, of a tendency

for a “red” and “white” opposition [13, 19, 20]; archeological evidence would imply that a tripartite opposition of red, black and white can be traced back to around 11,000 years ago, and thus many millennia before the verbal oppositions of these same three colors are confirmed in written sources. The first conceptually isolated color category might have been neither black nor white, but rather red; the distinction of “black” and “white” (possibly recognized earlier only as “light” and “dark”) may have been the consequence of metallurgy generating “purity,” so that white silver was conceptually distinguished after the cognitive recognition of “red” as a general category, different from “light” and “dark.” The division of “red” into several hues was the first step in the lexical partition of the spectrum, with the categorization of “black” and “white” only taking place over the last 5000 years, with white probably playing the role of cognitive catalyst, being the result of creating “purity” = silver = “white” – and leading to the identification of soot = refuse? = “black” as the opposite of purity = “white.” The black and white opposition can only be understood in terms of purity, and thus followed from earlier developments.

Salience, Convergence, Usage and Meaning

Chinese *bái* (“white”) is documented as an early color word (in Chinese – but more than a millennium after the earliest Ancient Near Eastern texts), largely focused in the color recognized today – and maintained throughout history, but *bái* is also associated with silver. In its final stage, the early Egyptian for “white,” *ḥdj*, is replaced by *ūbaš* (earlier meaning “to shine”). The salient meaning of *ḥdj* in Egyptian is the material silver, not the color word. The concept of “white” = “purity” = “silver” seems to be prevalent, and probably came from Mesopotamia.

In Chinese, the contemporary word for black, *hēi*, replaced *xuán*, the word for black used during the first millennium BC; evidence of historical salience for “red” in Chinese is likewise lacking, as the ancient term *chì* was abandoned and substituted with *hóng*. In Mycenaean Greek, the main word for “red” is *po-ni-ko-ro* (later *phonikós*, a loanword referring to the Phoenicians

who furnished the red dye) rather than *e-ru-to* (which gave rise to the Classical basic color term *eruthrós*).

Classical Greek *kuáneos* for blue still exists in Modern Greek, but has ceded dominance to *mple* = “blue,” a loan word – and thus blue is not salient, and the modern word a recent loan word. Materials and loanwords are more evident than salience, but the progression underlying the Berlin & Kay approach is based on independent abstract terms accumulating gradually and independently, and remaining stable. A rather uniform terminology has arisen – but through exchange of materials, loan-words and contact. The teleological approach works when projecting from the present back, but not when beginning with the origins and moving forward.

For Egyptian, Akkadian, and Sumerian (dating to before the middle of the second millennium BC), the color terminology did not match the colors used in art. In contrast to this, already for Mycenaean Greek and Classical Greek (thus, from the second half of the second millennium BC onward), “it is hardly surprising that in the use of color, language and representative art are two sides of the same coin” [20]. Thus, in comparing Bronze Age paintings with Roman-era painting, for Blakolmer, the use of color in painting reflects the development of a vocabulary in the Greek language. By comparison, in Egyptian art, there are many colors used in painting that are not accounted for by any kind of color-related vocabulary (Warburton in [7], also Blom-Böer in [11]).

The salience emerging from the first millennium onward depends on a fundamental change during the second millennium; this linguistic and cognitive change influenced later developments.

Color as Categorization

This discussion aims at the origins and early development of color terminology, rather than use. In general, philologists catch the color terms where they appear and not because the ancients systematically used colors as an elementary means of classification. Nor did the ancients

view gold, silver, lapis lazuli, turquoise, carnelian, jade, amethyst, and the like as ordinary products, but rather as extraordinary and unusual materials: the bones, flesh, and hair of the gods would be silver, gold, and lapis lazuli in ancient Egypt. Classical Greek divine statues are described as *xruselephantēlektros*, “of gold, ivory, and electrum”: attributes of divinity, not mere high-priced materials, but part of another world (stressed of Egyptian color conceptions by Schenkel in [11]). The process of creating color categorization involved demystifying and banalizing precious materials, rendering them cognitively flexible – betraying the divine origins.

Summary

The dominance of the Berlin & Kay Theory has blocked access to the understanding of how color terminology developed during the earliest stages. Precious materials and loanwords played a decisive role in forming the foundations for developing an early understanding of color beyond the simplest terms among the literate. In the earliest phase, the variety of terms for “red,” “green,” “yellow,” and “blue” probably preceded the expansion of color vocabulary beyond Berlin & Kay Stages III and IV. Account must be taken of the origins and development of early color terminology; recent convergence may likewise owe more to exchange and loanwords than to universalism. The use of ordinary materials to designate color is the final form of the process practiced after abstraction had come into existence. Developing abstractions was largely a matter of hue.

Definition

Comparative color categories are salient partitions in the perceived color spaces of primates that are known to vary when encoded by signaling systems that differ across species.

The Neurophysiology of Color Vision

The entire range of human color perception, in all its vibrancy, is due to the operation of just three types of photosensitive retinal cone cells and the neural mechanisms responsible for interpreting their signals. These cone cells contain photosensitive opsin pigments that preferentially absorb light at different wavelengths. The short-wavelength (S) pigment has peak absorption of light at about 430 nm, roughly corresponding to blue light; the medium-wavelength (M) pigment has peak absorption at about 530 nm, corresponding to green light; and the long-wavelength (L) pigment has peak

Evolution of Primate Color Vision, Fig. 1 Sensitivity curves for human photopigments (attribution: Vanessaekowitz at en.wikipedia)

absorption at about 560 nm, corresponding to red light (see Fig. 1).

Dysfunction in the cone cells or in the coding of their pigments leads to various types of color blindness. In humans, genes for S-type cones are located on chromosome 7, while those for the M- and L-type cones are located on the X chromosome. This largely explains why color blindness is a much more common phenomenon in men, as women possess independent copies of the M- and L-pigment genes on their two X chromosomes.

The M- and L-type pigments are nearly identical in their genetic specifications. The small difference in their light absorption profiles is due to a difference in only 3 out of 364 amino acids that code for their respective proteins [8]. The S-type pigment, on the other hand, is more distinct on the molecular level.

Each type of cone cell responds over a range of wavelengths, and the intensity of a cone's response to a light signal depends not only on that signal's wavelength but also on its intensity. This creates a situation in which the wavelength of a light signal cannot be uniquely identified based on the response of a single type of cone cell. Unique color information is only recoverable through the simultaneous and concerted action of different types of cone cells operating within a small neighborhood of each other.

In a sense, the response profile of each type of cone cell can be viewed as a “basis vector” that,

along with the other cones that make up the basis, defines a multidimensional color space. This analogy is made more concrete when considering the *color-matching* experiment that is foundational to the field of color science. In this experiment, observers are presented with a test light with an arbitrary spectral power distribution on one side of a bipartite white screen. The observers' task is then to try to match the appearance of the test light by individually adjusting the intensities of a series of primary lights focused on the other side of the screen. When a match is achieved, the lights on each side of the screen, while physically different in their spectral distributions, are perceived to be the same. Appearance-matched lights produced in this way are called *metamers*. There is a degree of variability among color-normal observers in the amounts of the three lights required to achieve a metameric match.

For people with normal color vision, exactly three primary lights are required to perform the color-matching task. As a result, normal human color vision is said to be three-dimensional or *trichromatic*. Establishing the dimensionality of color vision in nonhuman animals is an often difficult task requiring extensive training and testing of the animals [7]. A frequent practice in the literature – arguably justified – is to equate an animal's color vision dimensionality with the number of distinct color photopigments it expresses in its retina. However, the tarsier provides an example of a primate with a fairly uneven retinal distribution of its two cone types, challenging classical views about how color identification works through local networks of opponent cone cells [5]. The tarsier's labeling as a dichromat based on a photopigment-type count alone should therefore be done cautiously [7].

The Evolution of Primate Color Vision

It is believed that gene duplication and mutation of cone pigments, which ultimately made multidimensional perceptual color spaces possible, traces back to the time of the first vertebrates [1]. Almost all vertebrates have an S-type pigment very similar to that possessed by humans [8].

Most mammals have a single X-chromosome cone opsin gene, typically coding for a single long-wavelength visual pigment, and are *dichromats*. But even among primates, only the Old World monkeys, apes, and humans are *trichromats*, having a second – and highly homologous – cone opsin gene on the X chromosome, which codes for a medium-wavelength visual pigment [8, 12]. The generation of these red- and green-pigment genes is thought to have occurred following a duplication event after the split between the New World monkeys and the *catarrhines*, a group of higher primates made up of the Old World monkeys and apes (including humans), about 40 million years ago [12].

Opsin-gene and cone-pigment complements appear to be largely the same among the catarrhines [8, 12]. Psychophysical studies of macaques provided much early information on the color discrimination abilities of the Old World monkeys [7], and much of this research showed performance very similar to that of humans, suggesting a concordant perceptual color space [15]. Studies of chimpanzees also showed wavelength discrimination similar to human performance [4] (for a review, see [6, 7]).

Among the placental mammals, trichromacy appears to be found only in certain primates [7]. However, it is possible to enhance color discrimination behavior in dichromatic mammals through genetic engineering. Behavioral tests have shown strong evidence for novel color vision in mice genetically engineered to express the human L-opsin gene [9]. This suggests that the visual systems of traditionally dichromatic mammals can readily make use of higher-dimensional color signals.

Why, then, when traditionally dichromatic animals can be easily made to demonstrate three-dimensional color vision, is trichromacy seemingly restricted to certain primates? Further, why does trichromacy in primates manifest itself the way that it does, namely, with such a large spectral overlap between the M- and L-pigment sensitivities? Several hypotheses have been advanced to answer these questions. They are of two basic types: one focusing on the potential advantage of three-dimensional color vision in finding food and

the other suggesting that trichromatic color vision was selected for perceiving subtle, behaviorally relevant cues on exposed skin.

The experience of humans with various forms of reduced color vision suggested the hypothesis that color vision was selected for its benefit to detecting targets in visual scenes. Specifically, it has been conjectured that color vision is especially useful for detecting ripe fruit and edible leaves [11]. Consistent with this hypothesis is the observation that ripe fruit is more easily detected against a background of leaves in a trichromatic perceptual space [13]. Also, in one study, several species of frugivorous (fruit-eating) primates tended to eat and disperse seeds from fruit whose reflectance spectra are tightly clustered in the color space described by trichromatic catarrhine photopigments, while non-preferred fruit is more diffusely distributed in this color space [14]. In another study, folivorous (leaf-eating) trichromatic primates that were surveyed tended to eat leaves shifted more toward the red end of the spectrum relative to leaves eaten by non-trichromatic primates [10].

The food-based hypothesis suggests an obvious evolutionary advantage for primates. However, a question remains as to why catarrhine trichromacy is so uniform in its cone sensitivities given the wide ranges of diets – not all of them strictly frugivorous or folivorous – of these primates. An alternative hypothesis suggests that the specific tuning of primate color vision is selected for its advantage in detecting changes in the concentration and oxygenation of blood in conspecifics as indicated by subtle color shifts displayed on exposed skin [3].

Skin reflectance can be modulated over two dimensions according to oxygen saturation and concentration of hemoglobin in the skin [2, 3]. The effect of changes over the oxygenation-concentration dimensions results in shifts in skin reflectance that are predictable (see Fig. 2), with oxygenation modulations shifting hues across the red-green axis and concentration modulations shifting hues across the blue-yellow axis.

Particularly notable in this pattern of reflectance changes is that they occur exclusively in the region of color space at which the M and

Evolution of Primate Color Vision, Fig. 2 Skin reflectance changes due to varying oxygenation and concentration of blood

L pigments are maximally sensitive. That is, the characteristic “W” shape nestled within skin’s reflectance profile shifts its position in the region of peak sensitivity of the most recently evolved photopigments, which are nearly optimal for detecting this shift [3]. These shifts are also consistent across all skin types.

It has been observed that trichromatic primates tend to have either bare faces or large areas of exposed skin, such as a bare rump, a finding supportive of the skin-based hypothesis [3]. Further, dichromats are demonstrably poor at detecting changes in skin coloration [2]. Also, whereas the reflectance spectra of the collective primate diet vary widely, the shifts in skin reflectance across the oxygenation-concentration dimensions are stable across all primates [3].

More general shifts of skin color are often linked with various conditions of health and emotional status [3]. The skin-based hypothesis for trichromatic vision selection is unique in that it suggests a *social* advantage for catarrhine color vision. This advantage applies not only to maintaining the integrity of the social group through a sensitivity to health-related cues but also to perceiving threats from conspecifics, such as signs of aggression in the form of increased oxygenation of blood.

Fechner, Gustav Theodor

Mark D. Fairchild
College of Science, Rochester Institute of
Technology, Rochester, NY, USA

Gustav Theodor Fechner was a German experimental psychologist and philosopher. He is also considered by many to be the father of modern psychophysics. Initially, Fechner took a degree in medicine and worked in that area for a while. During that time he began publishing a series of humorous and satirical articles and poems lampooning the medical profession. These were published under the pseudonym Dr. Mises, and one of his most famous publications of this genre was on the *Comparative Anatomy of Angels* (1825). The writings of Dr. Mises certainly provide insight into the breadth and depth of Fechner's intelligence and abilities.

Fechner then moved on to physics by learning about contemporary advances in electricity and magnetism through translation of great French works as well as handbooks of chemistry and physics into German. With this new knowledge in hand, Fechner taught at the University of Leipzig, eventually obtaining a professorship and making distinguished contributions to the field. Interestingly, Dr. Mises also continued to publish on occasion.

All along, Fechner was interested in the mind-body problem and desired to determine an empirical relationship between the physics of the world (and body) and the perceptions of the mind. Some of his studies in this vein included the discovery of perceived colors for slowly flickering black-and-white patterns

(known as Fechner's Colors or Fechner-Benham Colors after Benham made the work accessible in English) and the detailed study of color afterimages. It was the study of afterimages that set Fechner off in his next direction. He was studying afterimages by staring at the sun through colored filters. This led him to give up his chair in physics in 1840 due to induced photophobia from eye injuries that made him an invalid, and overly sensitive to light, for about a decade.

During this period, on October 22, 1850, while lying in bed he finally figured out the basis of linking physical measurements in the environment with human perceptions in the mind that is currently referred to as Fechner's law. Based on his knowledge of Weber's law (coined by Fechner) that, for many perceptions, the ratio of a just-noticeable change in a stimulus to the initial magnitude of a stimulus is a constant, Fechner figured out that the differential equation implied by Fechner could be integrated and assumed that the just-noticeable differences could be summed to predict perceptual magnitude. The resulting relationship, now termed Fechner's law, mathematically suggested that the magnitude of a perception would be proportional to the logarithm of the stimulus intensity.

More modern knowledge tells us that the specific relationship depends on the perceptual quantity and that it is not valid to sum JNDs to predict magnitudes. Nonetheless, Fechner's contribution was very significant in founding the field of psychophysics. Fechner published further details of the theory and practice of psychophysics in his seminal work, *Elements of Psychophysics* (1860), [1] which remains a useful guide for practitioners in the field. Interestingly, Fechner is also credited with being the first to introduce the concept of the median to formal data analysis.

From Boring's introduction in Adler's translation of *Elements of Psychophysics*, we find that Fechner was for 7 years a physiologist (1817–1824), for 15 years a physicist (1824–1839), for 12 years an invalid (1839–1851), for 14 years a psychophysicist (1851–1865), for 11 years an experimental estheticist (1865–1876), and for periods throughout a philosopher.

Definitions

Fechner colors refers to the illusory colors that result from the repeated flashing of black and white patterns. These colors are often referred to as Fechner colors who is often given credit for their discovery.

Benham's top is a pattern developed for a spinning disc to create illusory colors that have become a standard.

Basic Phenomenon and History

Fechner colors refers to the creation of illusory or subjective colors through an alternating pattern of black and white stimulus. The first report of these subjective colors was by Prevost, a French monk [5]. He used a white light and put a white sheet of paper to break the beam periodically to generate the illusory colors. Fechner is often reported as the discoverer of this illusion and his name has been given to these illusory colors. Fechner's creation of the subjective colors was accidental as he was at the time was involved in the creation of discs to create different shades of gray [1, 5] (Fig. 1a). Fechner was the first to use a spinning disc as

Fechner's Colors and Benham's Top, Fig. 1 Discs used to create subjective colors. (a) One used by Fechner, (b) one used by Benham, (c) a common one based on Benham's work

F

the means for creating these illusory colors. There were several studies throughout the nineteenth century of this phenomenon with spinning discs including by such a luminary as Helmholtz. Helmholtz even proposed the early explanations for these colors. Each of the early studies had used individually designed discs to create the illusory colors. In 1894, Benham developed what has become the near standard disc pattern of producing these illusory colors that he called the “artificial spectrum top” and has come to bear his name [2]. This disc is called usually either Benham's top or Benham's disc. Figure 1 shows some examples of the discs that have been used, including the one by Fechner (Fig. 1a), one by Benham (Fig. 1b), and another common one derived from Benham's (Fig. 1c). Variations in the disc include having thicker single lines or thinner three parallel lines.

To generate these illusory colors, it is important that the flicker rate of the stimulus is not too slow or too fast. The flicker is noticeable and the stimulus is well short of the critical fusion frequency. The rate of alternation of the black and white areas is not terribly high with effective stimuli frequencies going from 3 Hz on up with optimal rotational frequencies for the spinning disk of about 4–6 Hz [3, 4]. The direction of the spinning seems to effect the colors experienced [11].

Creating and Measuring Fechner Colors

To create Fechner colors, the disc is usually spun in the frequencies reported above. Colors are

experienced in bands located where the black lines will be flickering. While Benham's top represents a traditional means of creating the colors, researchers have developed many alternatives in trying to understand how these illusory colors occur [4, 8, 10, 11]. It is also not a necessity that a spinning disc or top be used. A stationary flickering stimulus can be used as [8] though there is some evidence that the colors are not as easily seen [10]. To see an online example that uses a flickering stimulus the reader is referred to Krantz [9].

Measuring the colors produced by Benham's top has been approached several ways over the years. The most common methods use some form of color matching to determine the color experienced by the participant. Schramme [12] used a color matching paradigm where a mirror was used to overlay the color patch onto the spinning disc. Then participants tried to match this patch to the illusory colors they were seeing. Rosenblum, Anderson, and Purple [10] used Munsell color chips to make the color matches which served them well as they were interested if the illusory colors show some of the features of color matching errors seen in dichromats. Jarvis [8] used a binocular matching method where the illusory colors were presented in one eye and the matching color was presented in another eye. In all of these methods, the attempt was to try to determine the color perceived by the observer.

Results from various studies over the years have revealed several interesting features of Fechner colors. First, the colors experienced are always desaturated, that is somewhat washed out

[8]. These colors can vary in their vibrancy in ways that depends upon the method of generation, but natural colors can much more easily be made to be highly saturated. Many reports indicate a wide range of individual differences in the colors experienced [7]. While most visual phenomena have some individual variation, there is a remarkable degree of agreement across observers. If there were not this agreement, then technologies such as color reproduction would not be feasible. This agreement is not seen in Fechner colors. Other researchers have observed that both illumination level and adaptation state alter the colors experienced, making the adaptation state of observers important to control in any experiment on Fechner colors [3, 4]. Perhaps one of the most interesting findings is that Fechner colors can be obtained with monochromatic, single wavelength, illumination as well as in full-spectrum neutral illumination [3].

Explanations and Future Directions

There have been many different types of explanations offered for the existence of Fechner colors in the almost 200 years since its discovery [6]. The challenge for any theoretical explanation is twofold: how does a monochromatic or neutral color stimulation can lead to the perception of colors, and what is the role of the flickering rate. Another important factor to consider, often ignored in most theoretical attempts, is the individual differences in the colors reported by observers. Older explanations have involved fatigue in receptors, the role of complementary colors, and even factors related to Hering's original theory of color perception. Most of these explanations have been ruled out by directly examining fatigue, contrast, and the limitations of the complementarity of the colors experienced [1]. As more information about cone functioning developed, explanations developed that used ideas about differences in the speed with which different wavelengths of light are processed [3] and information about the relative speed with which the blue or short-wavelength cone responds to flickering stimuli compared to the speed of the other cones respond to the same

flickering stimuli have been developed. The hypothesis is that it is the relative slowness of the short-wavelength cone in responding to flickering stimuli that is responsible for Fechner colors. The idea is that with slowly flickering stimuli, the short-wavelength cone responds too slowly to pick up the flicker adequately while the middle and long wavelength cones, red and green cones, respectively, still can respond. Thus, these cones do not adequately cancel each other out in the blue-yellow color opponent channel leading to the perception of colors. Schramme [11] found, using color matches, Fechner colors that fell along the blue-yellow axis of the 1931 CIE diagram that matched these expectation.

Despite the sophistication and intuitive plausibility of this explanation, it is still safe to say that there is no generally accepted explanation for these illusory colors. Campenhausen et al. [4] propose a two-step model for Fechner colors that involves both summing of cone inputs in a non-color opponent pathway and lateral interactions at the level of the horizontal cells. The support for this hypothesis comes from many lines of evidence but includes that Fechner color in areas that do not receive modulated light and that achromatic effects similar to Fechner colors can be produced in rod vision. Schramme [11], whose results seemed to support the possibility that Fechner colors were due to the slowness of the short-wavelength cone, proposed that Fechner colors actually arise in the blue/yellow ganglion cells. The argument here depended upon the ability to manipulate the perceived Fechner color along the blue-yellow axis of the CIE diagram in a manner would have been hard to predict from the action of the short-wavelength cone alone. Using these two explanations as examples, it can be seen that even the level of the visual system involved is not agreed upon, though all theories do seem to argue that Fechner colors arise in the retina.

While these explanations are intriguing, future developments will be needed to combine, modify, or seek a new direction of explanation for Fechner colors. One feature of the findings that is rarely explained and needs to be is the relative range of individual variation in the colors experienced. The actual mechanism of the temporal response

needed to be further uncovered as this finding increases the evidence for multiple ways that the eye responds to temporally moving or flickering stimuli. It is possible that it is in the variations in temporal response that the individual differences of Fechner colors lie.

Definition

A ferroelectric liquid crystal (FLC) is one in which the molecules that constitute the material are chiral, possess a dipole moment in the direction which is perpendicular to the long molecular axis, and are tilted with respect to the formed layers. This is characteristic of the smectic C* liquid crystal. They have application in a number of photonic and display devices.

Applications

Fast tunable photonic elements are one of the hot research topics these days. Thus, liquid crystals have become attractive for applications such as diffractive optics, adaptive optics, or optical metrology [1]. While nematic liquid crystal (LC) devices are the dominant technology, because of its easy manufacturing, devices based on ferroelectric liquid crystals (FLCs) have grown in importance because they can switch up to 100 times faster than standard nematic LCs at the cost of less power consumption [2]. FLCs have found applications in diffractive optics for the generation of digital holograms, adaptive beam steering systems, and polarization gratings. Additionally, high-speed communication systems and producing elements (such as switches, attenuators, and polarization rotators) demand extremely fast response, stable, low loss, operable over a wide temperature range, and that require small operating voltages and extremely low power consumption. Thus, fast switching ferroelectric liquid crystal (FLC) is a good candidate for the new generation of photonic and display devices, which proved to be better in response time, than usually used nematic LC. However, the FLCs are less popular for real applications because of difficult alignment process [3–10].

The photoalignment technology enables the key problems usually faced in FLCD applications to be solved [11], such as (i) quality of FLC alignment on sufficiently large surface area; (ii) appropriate adjustable anchoring energy and pretilt angle; and (iii) low losses in the alignment layers due to their small thickness. The further development of novel photoaligned fast ferroelectric LCD and photonics devices aimed at (i) fundamental study of the new appropriate electrooptical modes used for switching such as electrically suppressed helix (ESH) FLC and deformed helix FLC (DHFLC); (ii) understanding of physical mechanisms of FLC interaction with a photoaligned surface of different photosensitive nature (diffusion, photocrosslinking, and photo-degradation) to produce a stable alignment with a controllable anchoring energy and pretilt angle over sufficiently large

surface area; (iii) development of new fast response FLC materials with fast switching and low power consumption; (iv) elaboration of fast response optical FLC elements for photonics applications, such as switches, grating, Fresnel lens, Circular Dammann (CD) grating, attenuators, and polarization rotators; and (vi) investigations of regimes of operation to allow to use efficient addressing of FLCD.

The response time of conventional LC devices is still inferior to the existent competing technologies. The target LC cells' response time for various photonic and display devices is time < 1 ms to provide a high resolution, low power consumption, and extended color gamut LC displays. Fast switching FLC is a good candidate for the new generation of liquid crystal display and photonics devices, which proved to be much better in response time than usually used nematic LC. The problems, which are usually faced in FLCs such as (i) quality of FLC alignment on sufficiently large surface area; (ii) appropriate adjustable anchoring energy and pretilt angle; and (iii) low losses in the alignment layers due to their high thickness of the alignment layer, etc., can be effectively solved by a photoalignment technology. Multistable electrooptical modes were shown to exist under certain conditions in photoaligned FLC cells, which mean that any light-transmission level can be memorized after the driving voltage is switched off. High-frequency hysteretic free electrically controlled $0-2\pi$ phase modulation of the light can be implemented using a very short helix pitch (less than 200 nm) DHFLC. The application of fast V-shaped DHFLC for new active-matrix LCD and optical data processing devices is envisaged. On the other hand, the ESHFLC mode manifests saturated electro-optical up to frequency 5 kHz at the electric field of 1 V/ μm .

At the same time, application of FLC for high-speed communication systems, enables elements (such as switches, attenuators, and polarization rotators) that are extremely fast, stable, durable, of low loss, and operable over a wide temperature range, and require small operating voltages and extremely low power consumption when using bistable and multistable switching

with optical memory. Passive FLC elements for fiber optical communication systems (DWDM components) based on LC cells can successfully compete with the other elements used for the purpose, such as micro electromechanical, thermo-optical, opto-mechanical, or acousto-optical devices.

The prototypes of the novel photoaligned FLC photonic elements may include high resolution, low power consumption, and high efficiency, which can be used for the beam-steering devices, lens, microdisplays, and other adaptive optical elements. The switchable lenses based on new FLC prototypes can be efficiently applied in the new generations of switchable 2D/3D LCD TV. Thus, developed fast and low power-consuming FLCs can also be deployed for the Field Sequential Color (FSC) FLC microdisplay, which is now one of the most advanced technologies, for pico-projectors can be also made on the basis of new materials and electrooptical modes in FLC to be developed in the project. The modulators and switches based on fast responded FLC are envisaged in Dense Wavelength Division Multiplexing (DWDM) elements of optical communication systems, such as switches, filters, attenuators, equalizers, etc.

Recent Developments

An extensive work studying optical and electro-optical response of FLC, as well as developing new FLC materials with advanced surface alignment, has been conducted. A good progress in formulating new photoalignment materials that are potentially capable of being used in photo-aligning technology for LCDs was made. The aligning materials developed at HKUST are based on photo-polymerized and cross-linked dye photosensitive layers that enable the following: (i) high order parameter >0.8 ; (ii) excellent alignment quality of LCD with a high contrast ratio in TN, VAN, π -BTN, and FLC modes; (iii) high temperature stability up to 230 °C suitable for LCD manufacturing; (iv) UV-stability due to the polymerization and cross-linking effect in dye

layers; (v) perfect adhesion and high azimuthal and polar anchoring energy, i.e., $>10^{-4}$ J/m², which is the same as the anchoring of the rubbed polyimide (PI) layer; (vi) excellent sensitivity with a minimum energy of 150 mJ/cm² for a nonpolarized obliquely incident light and 20 mJ/cm² for polarized light, allowing roll to roll processing of retardation films and polarizers; and (vii) the value of voltage holding ratio (VHR) for the photo-aligned LC cell ($>99\%$ at 80 °C) and residual DC voltage (<50 mV) was found to be even better than those for rubbed PI layers.

Fast switching FLC with V-shape switching, with a number of gray scales, which can be used, on the basis of field sequential colors (FSC) FLC LCD have been developed. Several FLC electro-optical modes for the matter have been employed, including electrically suppressed helix (ESH), deformed helix ferroelectric (DHF), and vertical aligned DHF (Kerr effect) modes. Novel photo-aligned FLC devices may include FSC FLC with a high resolution, low power consumption, and extended color gamut, which can be used in the screens of portable PCs, mobile phones, and PDAs. The switchable goggles and lenses based on new FLC prototypes can be efficiently applied in the new generations of switchable 2D/3D LCD TV. FSC FLC microdisplay, which is now one of the most advanced technologies for pico-projectors, can be also made on the basis of new materials and electrooptical modes in FLC.

Fast ferroelectric LC (FLC) are applied for high speed communication systems, producing elements (such as switches, attenuators, and polarization rotators) that are extremely fast, stable, durable, of low loss, and operable over a wide temperature range, and that require small operating voltages and extremely low power consumption when using bistable and multi-stable switching with optical memory. Passive FLC elements for fiber optical communication systems (DWDM components) based on liquid crystal (LC) cells can successfully compete with the other elements used for the purpose, such as micro electromechanical (MEM), thermo-optical, opto-mechanical, or acousto-optical devices.

Definition

Textile finishing can be defined as all processes (chemical and/or mechanical), employed subsequent to textile coloration which impart additional functionality/superior aesthetics to the textile material. Mostly, textile finishing is applied to fabrics (woven, knitted, nonwovens); however, textile finishes can also be applied to fibers and yarns.

Introduction

The primary objectives of textile finishing are to improve the aesthetic and functional properties of textiles. In a broader sense, “finishing” relates to all processes that fabrics might be subjected to subsequent to weaving, knitting, or nonwoven manufacturing processes. The term “finishing”

could include fabric preparation (e.g., singeing, desizing, scouring, bleaching, optical brightening process, mercerization process, etc.) and coloration (dyeing and printing); indeed, the combination of these processes is sometimes referred to as “wet-finishing” processes [1]. Another school of thought refers to “finishing” as the final stage of fabric preparation with the objective to prepare the fabric for the consumer and that the term “finishing” concerns only fabric treatment other than fabric preparation and coloration. In this chapter, finishing subsequent to coloration will be discussed, in which context, it is important to check the compatibility of the finishing process with the treated substrate and the coloration process that has been previously implemented [2].

Classification

The conventional textile finishing methods can broadly be divided into two categories:

- (i) “Dry” or “mechanical” finishes
- (ii) “Wet” or “chemical” finishes

There are, however, finishing operations which combine mechanical and chemical finishes e.g., mercerization (the NaOH treatment of fabric on machines with or without tension).

“Dry” or “Mechanical” Finishes

The mechanical finishing of textiles may range from a simple drying operation to a complicated series of calendaring operations (Schreiner finisher). A few examples of the mechanical finishing of textile are discussed below.

Drying

It is well known that wet fabric can hold a large amount of water and that some of this held water can be easily removed by simple mechanical action. The efficiency of the process to mechanically remove the water from the fabric is vitally important from both cost and environmental points of view. High energy is required to

evaporate the remaining water due to its high latent heat of evaporation. Machines such as mangles, centrifuges, and suction-slot machines are used in textile processing to remove water from fabric by mechanical means [3]. Drying machines are employed in textile processing with the purpose of removing the water that has not been removed by mechanical action. The majority of the dryers used in textile processing offer continuous throughput and a few examples of such machines are “hot flue”, “drum dryers”, “perforated drum dryers”, “tumble dryers”, etc. [1].

Calendering

In calendering, the fabric is passed between two heavy rollers. The rollers may vary in hardness, surface speed, and temperature. Fabric properties such as smoothness and luster can be improved using calendering [4]. Calender finishing can be of six types, namely, simple finishing or swizzing calendering, chasing calendering, friction calendering, Schreiner calendering, embossing calendering, and felt calendering. A few examples of calendering are discussed below.

Friction Calendering

The differential speed of the two rollers is carefully selected to produce effects such as “chintz.” The smooth metal roller normally rotates at a higher rate than the soft roller [1, 3]. Durable finishes (Everglaze) can be achieved using this method by adding a cross-linking agent [5].

Embossed Effects

In this technique, a fabric pattern is produced by calendering the fabric using an engraved heated metal roller and a soft roller [4]. To avoid slippage between the rollers, it is important to control the process accurately.

Schreiner Finishing

In “Schreiner,” fine lines engraved on a metal roller are transferred to the fabric. With appropriate fabric construction and by carefully engineering the line direction of the engraving, a soft lustrous handle can be achieved [3]. This treatment is used to give cotton fabric the appearance of silk [1]. Although the wash fastness of this

effect is poor [1, 3], it increases the point-of-sale appeal [3].

Napping

Napping is a very effective way for imparting a soft handle to fabrics [6]. Fabrics of low-twist, staple fiber yarn can be used for napping [7]. The napping machine contains metal cards and the napping tool comprises rollers with curved metal wires [1] which pull the fiber ends to the surface of the fabric. One or both sides of the fabric can be napped [7].

Sanforizing

Fabrics contain internal tensions as a result of the various manufacturing processes employed, and a pretreatment is required to nullify this effect, since, otherwise, there is a possibility of significant shrinkage of garments during washing. Sanforizing is a controlled mechanical shrinkage process without the use of any chemicals. This treatment should be the last treatment that is applied to the fabric [1].

“Wet” or “Chemical” Finishes

Although chemical finishing has always been an important process for textiles, the demand for high-performance textiles has grown exponentially in recent years and, as a result, so has the demand for chemical finishing [8]. The majority of chemical finishes for textiles are additive, where the finishing treatment results in an increase in substrate mass through sorption or deposition of chemical compounds. However, some chemical finishing can be *subtractive*, in which the treatment results in the fiber substrate losing mass as a result of chemical degradation. While chemical finishing is mainly applied to fabric, it can also be applied to loose fibers, yarns, garments, etc. Based on the life-span of the finish on the textile substrate, textile finishing can also be classified as *transient* and *durable* finishing. The most important aspect in this regard is the resistance of the finish to domestic washing [9].

Application of Chemical Finishes

While the application and formulation of chemical finishes depends on several factors, the most important factors are the composition of the material being treated and the chemistry of the functional chemical. Interaction of the finishing effects, compatibility of different chemicals, and the environmental/green credentials of the process are other factors to consider.

If the functional chemical finishes displays high substantivity towards the substrate, then exhaust (immersion) application methods can be used and any of the textile dyeing machines employed for batchwise dyeing can be used for textile finishing. However, if the applied functional chemical has limited or low substantivity, then a continuous application method can be used. One such method is the pad-dry-cure method wherein the fabric is first immersed in a solution containing the functional chemical, followed by drying and finally “curing” to fix the finish within the fabric (Fig. 1).

Chemical finishes can also be applied to textiles using modern application techniques such as exposure of the textile substrate to plasma employing either low pressure, low-temperature plasma, or atmospheric plasma. Plasma, which is considered as the fourth aggregation state of matter, can be described as a mixture of partially ionized gases in which the constituents are achieved by external energy addition. The main advantage of such plasma treatments are:

- It consumes minimal chemicals compared to conventional finishing.
- No costly drying process is required.
- It is a surface treatment, so the bulk properties of the material are not affected.
- High environmental compatibility.

Important Chemical Finishes

A few commercially important chemical finishes are discussed below. Other types of chemical finishes include, but are not limited to, antistatic finishes, soil release finishes, insect resist finishes, flame-retardant finishes, stain resist finishes, non-slip finishes, UV-protection finishes, finishing to improve color fastness, etc.

Finish, Textile,**Fig. 1** Schematic diagram of pad-dry cure operation

F

Softening Agents

Softeners are one of the most widely used chemicals in textile processing, and as the name suggests, the application of softeners dramatically improves the handle and perceived quality of a fabric. In textile processing, one of the most important functions of softeners is to counteract the harshness imparted by other finishes (e.g., easy care). Softeners are, however, also used extensively in domestic washing formulations.

Although the main effects of the softeners are at the surface of fibers, the small molecules can impart internal plasticization of the fibers by reducing the glass transition temperature (T_g) of the fibrous polymer [8]. Early softeners were based on waxes and oils although modern types can be divided into five categories, namely, cationic softeners, nonionic softeners, anionic softeners, reactive softeners, and amphoteric softeners [3].

Cationic softeners are the most important type of softener for both industrial and domestic applications. The positively charged ends of the cationic softeners orient themselves towards the negatively charged fibers (zeta potential), creating a new surface of hydrophobic carbon chains that are responsible for the excellent softening effect of cationic softeners [8]. Because of the positive charge, these softeners are substantive towards cellulosic fibers, and exhaust application of these finishes is widespread using conventional textile dyeing machines (e.g., winch, jet, beam) [3]. Cationic softeners are known to exacerbate the soiling propensity of fibers

**Finish, Textile, Fig. 2** Dimethyldistearylammonium methosulfate

and to inhibit soil removal. Dimethyldistearylammonium methosulfate is a good example of a popular cationic softener (Fig. 2). The use of silicone-based finishes in textile processing has grown steadily over the last 50 or so years [3]. Silicon-based cationic softeners provide a high degree of softness and a unique hand to fabrics. However, silicon softeners may contain variable amounts of siloxane oligomers, depending on the method of synthesis, which may be a cause of air pollution [8]. A popular range of silicon softeners are based on the weakly cationic amino functional siloxanes. Although these silicon compounds could potentially be applied from mild alkaline conditions, durability is improved by application at pH of 4.

Nonionic softeners are well known to perform multiple functions such as softeners, emulsifiers, stabilizers, extenders, and lubricants [3]. Paraffin waxes and similar materials are the most basic

Finish, Textile, Fig. 3 Polyethylene

Finish, Textile, Fig. 4 Polydimethylsiloxane

nonionic softeners. Molten polyethylene (Fig. 3) at high pressure can be air oxidized to secure hydrophilic characteristics (mainly carboxyl groups). High-quality, more stable products can be produced by emulsification in the presence of alkali. These products are stable to extreme pH conditions and can withstand the temperatures used for normal textile processing [8]. In recent years, polysiloxanes have gained importance as nonionic softeners (Fig. 4). Due to their limited substantivity, nonionic softeners, with very few exceptions, are normally applied by non-exhaust methods (e.g., padding) [3].

Anionic softeners, due to the presence of the negative charge, are repelled from negatively charged fibers (e.g., cellulosic fibers) which leads to higher hydrophilicity [8]. These were among the first soft finishes to be used commercially and include long-chain alkyl sulfates, sulfonates, and succinates. Anionic softeners are used in specialized areas of application where the physiological activity is low, e.g., medical textiles. As the majority of fluorescent brightening agents are anionic, they are widely used in conjunction with anionic softeners for the resin finishing of white cellulosic fibers [3].

Reactive softeners contain functional groups capable of reacting with particular functional groups in some fibers [8] (e.g., the -OH group of cellulosic fibers). This type of finishing is permanent to washing due to the formation of covalent bonds between the softener and substrate.

Finish, Textile, Fig. 5 N-methylol derivative (R: C₁₇H₃₅)

Finish, Textile, Fig. 6 Compound containing silanol group

Finish, Textile, Fig. 7 Alkyldimethylamine oxide softener (R: long alkyl chain)

N-methylol derivatives of stearic acid amides and urea-substituted compounds are very successful as reactive softeners (Fig. 5) [3]. One example of a silicon-based reactive softener is given in Fig. 6, which is a modified siloxane and contains functional silanol groups. The silanol group could potentially be replaced by other functional groups such as amines or alcohols.

Amphoteric softeners have limited textile applications but are very popular in personal care products (e.g., shampoo formulations) due to their low toxicity [3]. One example of an amphoteric softener is shown in Fig. 7.

Water and Oil-Repellent Finishes

There is a distinction between “water-repellent” and “waterproof” fabrics. Waterproofing is achieved, for example, by coating the fabric with rubber. Such a treated fabric will not only be impermeable to water but also most notably against air and perspiration; as such, “waterproof” fabrics are uncomfortable to wear. A water-repellent finish, on the other hand, remains permeable to air and is achieved by the application of

Finish, Textile, Fig. 8 Polydimethylsiloxane

hydrophobic chemicals to the fabric [1]. These types of “water-repellent” finishes are normally used for clothing and will be discussed in this chapter. As very few textiles are inherently water repellent but none are oil repellent, so an additional process must be added to display these properties.

If the internal cohesive interactions within a liquid are lower than the adhesive interactions operating between a solid surface and the liquid, then a drop of the liquid will spread on the solid surface. Based on this theory, repellent finishes (both oil and water) work on the principle of reducing the free energy of the fabric surface [8]. In this context, it should be mentioned that alongside the chemical composition of the material, the geometry of the textile surface also plays a significant role in the wettability of the textile [1]. It has long been recognized that superhydrophobic surfaces require a unique combination of two fundamental properties, namely, surface roughness and low surface energy [2]. The functional chemicals used to achieve water-repellent finishing significantly vary in their chemistry, their role being to reduce the surface energy of the fabric by adding lower surface energy chemical groups to the surface [3].

The chemicals traditionally used to achieve water repellence may be divided into a few groups: metal salts, soap/metal salts, wax, pyridinium-based finishes, organometallic complexes, *N*-methylol derivatives, silicone finishes, and fluorochemical finishes [3]. Among these, only fluorocarbon finishes are known to repel both oil and water [3, 12], whereas the other finishes can repel only water. Moreover, perfluorinated derivatives are effective at very low concentrations [1]. Polymeric fluorochemical finishes are typically acrylic or methacrylic polymers with perfluoro side chains.

Silicon-based water repellents are also used (Fig. 8).

Easy-Care and Durable Press Finishes

As the name suggests, “easy care” and “durable press” are applied to textiles to impart minimum care properties, mostly to cellulosic fibers and their blends with other fibers. Various terms have been used to describe this area, including easy care, easy-to-iron, no iron, crease resistant, wrinkle resistant, wrinkle free etc. However the technically correct term is “cellulosic anti-swelling” or “cellulosic cross-linking” finishes [8].

Cellulose (natural or regenerated) is a linear polymer formed by the condensation of β -D-glucopyranose that contains 1 $\rightarrow$ 4-glycosidic linkages. The presence of hydroxyl groups along each chain creates extensive H-bonding both between (intermolecular) and within (intramolecular) the chains. Formation of such intramolecular H-bonds imparts “stiffness” to the cellulose molecules by restricting movement of the 1,4- β -D-glucopyranose units. The -OH groups are also responsible for the hydrophilicity of cellulosic fibers; owing to the high density of the -OH groups, cellulosic fabrics shrink in water and crease upon drying. The main function of easy-care/durable press finishing is to overcome shrinkage and wrinkling by cross-linking the -OH groups.

Although finishing agents are unable to penetrate the crystalline regions of the fiber, the easy-care/durable press finish needs to be of small M_r and preferably high reactivity to enable it to penetrate the amorphous region of the fibers [3].

It was demonstrated in the late 1920s that thermosetting resins (e.g., phenol-formaldehyde, urea-formaldehyde) could impart crease resistance to cellulosic fabrics. Since then, numerous publication and patents have described novel

Finish, Textile, Fig. 9 Dimethylolurea

Finish, Textile, Fig. 10 Methoxymethylmelamines (R=CH₂OCH₃, CH₂OH)

cross-linking reagents based on urea-HCHO chemistry [4]. This original type of easy-care products (urea-HCHO resins) used to contain high free formaldehyde, e.g., dimethylolurea (DMU) which is prepared from an excess of HCHO (Fig. 9). These nonreactant types of finishes are only durable to washing temperatures up to 60 °C. Wash fastness can be improved by using reactive resins such as methoxymethylmelamines (Fig. 10).

The first cyclic urea-reactant finishing agent was dimethylol ethylene urea (DMEU) which displays poor fastness to chlorine bleaching and adversely affects the light fastness of the finished fabric (Fig. 11). Cyclic urea-based finishing agents, *N,N'*-dimethylol-4,5-dihydroxyethylene urea (DMDHEU), comprise ~90% of the easy-care/durable press finish products that are available in the market [8] (Fig. 12). Due to the presence of two hydroxyl groups at the C-4 and C-5 positions, the reactivity of DMDHEU is low, and therefore, reaction requires a catalyst. Although DMDHEU-containing products contain >0.3% free formaldehyde, the search for formaldehyde-free finishing agents has spanned several decades [3] due to the toxicological effects

Finish, Textile, Fig. 11 Dihydroxymethyl ethylene urea

Finish, Textile, Fig. 12 *N,N'*-dimethylol-4,5-dihydroxyethylene

Finish, Textile, Fig. 13 *N,N'*-dimethyl-4,5-dihydroxyethylene urea

associated with formaldehyde. Textiles containing a high level of formaldehyde can give rise to eczema and allergic reactions; furthermore, HCHO is a suspected human carcinogen [8]. Expensive formaldehyde-free finishing agents such as *N,N'*-dimethyl-4,5-dihydroxyethylene urea (DMdDHEU) (Fig. 13) is used for textile processing. DMdDHEU is less reactive than DMDHEU and therefore requires a stronger catalyst and harsher reaction conditions for successful cross-linking with cellulosic fibers.

Antimicrobial Finishes

Antimicrobial finishes are used to inhibit the growth of or to destroy microscopic organisms [3]. This could be for hygiene purposes, i.e. to

Finish, Textile, Fig. 14 2-(2,4-dichlorophenoxy)-5-chlorophenol

protect the user from pathogenic or odor-causing microorganisms or to protect the textile material itself from damage caused by mold, mildew, or rot-producing microorganisms. Formaldehyde is a widely used biocide and preservation product. As discussed in the previous section, the majority of easy-care/durable press finishes contain HCHO, and therefore, these finishes display a small antimicrobial effect. However, for effective antimicrobial action, specific chemical finishes are used. Traditional antimicrobial agents such as copper naphthenate, copper-8-quinolate, and numerous organomercury compounds are strictly regulated because of their toxicity and potential for environmental damage [8].

A common antimicrobial agent extensively used for cellulosic material is polyhexamethylene biguanide (PHMB) which has long been used in applications such as cosmetics and swimming pools. Along with conventional textile applications, PHMB can also be used in the production of medical textiles. PHMB is cationic and therefore displays excellent durability on cellulosic material [3]. Triclosan (Fig. 14) is another antimicrobial agent that is used extensively in mouthwashes, toothpastes, deodorants, and on textiles. This is nontoxic to humans and used as durable antimicrobial finish on polyester and polyamide fibers and their blends with cotton and wool. Heavy metals such as silver, copper, and mercury can provide antimicrobial effect in the form of the metal or metallic salt. Antimicrobial high-performance textile fibers (e.g., polyester, nylon, etc.) can be produced that include nanoparticles of heavy metals (e.g., silver). Chitosan is a natural

biodegradable polymer which is nontoxic and shows microbial resistant.

Conclusions

As a result of increasing demands for superior quality and functionality in textiles, the sophistication of textile finishes and finishing operations has increased. New types of finishing are being developed to provide novel effects such as fragrance finishes, well-being finishes, bionic finishes, as well as finishing for smart textiles, medical textiles etc. Parallel to the search for novel finishes, existing finishes (and application techniques) are constantly being scrutinized to ensure that processing is as efficient as possible from technical, economical, and ecological perspectives. Textile finishing can be expected to remain a highly valuable tool which can significantly enhance the value of the finished textile product.

Definition

The use, informative, and aesthetic impact of color on humans and the environment.

Color and Function

Human environment may be considered as a system, since man and environment elements are mutually determinant in any sense – an interrelation concerned with demand of man for his environment. The function of the built environment is based on social demand, necessity raised to a social level.

Within the system of man and elements of his environment, structural relations are defined and

Antal Nemcsics: deceased.

sustained by complex functions. This complex is composed of three types of functions: utility, aesthetic, and informative ones. Utility function is understood as the designation and purpose of environment elements. Aesthetic functions bring about properties of environment elements which enable one to experience utility functions. Informative functions involve properties of environment elements by which their functions, uses, and operation become understandable for man. These preliminaries underlie the present day approach to environment color design, considering the totality of utility, aesthetic, and informative functions as the system of demands.

Environment color design has to serve the expression of the complex function of environment elements. Various functions of color-bearing environment elements are strictly interrelated and are prone to change into each other, a characteristic to be considered in the methodology of environment color design as a design process. It is necessary to develop design methods suitable for simultaneous and differentiated consideration and coordination of these components [1–3].

Color function components of environment color design as a design process can be deduced from the man to color relations. The man to color relation cannot be regarded in an abstract way. Colors are always associated to some object, phenomenon, or process, implicating into this relation their complex functions. In this respect, the theory of environment color design has been concerned with the possibility to express function by the color of the environment element. It can be stated, for instance, that more saturated colors of the color space, with longer dominant wavelengths, act dynamically and hence suit to express functions involving dynamism. The less the saturation of these colors, the lower their dynamism. The greater the hue, saturation, or lightness differences between members of color complexes to express a function, the more dynamic is the function expressed by them. The intensity of the expression of function is more affected by the variation of lightness differences than by saturation differences. Again, it is found that a function is expressed not so much by a single color but by a complex of several colors. Accordingly, the

expression of function by the environment elements contributes to harmony relations of colors borne by the element, and Coloroid color harmony relations may be combined with function expression indices [3, 4].

Disclosure of the rules of function expression cannot rely solely on visual information, since it is physiologically possible that stimuli perceived by one of the sensory organs should create perceptions normally transmitted by another sensory organ.

Utility Function of Colors

Environment is the space for human activities aimed at satisfying human demands. Since the beginnings of society, architecture has been expected to meet human demands. Analysis of and reckoning with functions necessarily took place in every period, even if functional demands have significantly changed and developed through the ages. The scientific analysis of functions and a conscious, integrated attention to all the requirements could not, however, develop earlier than in contemporary age, at a higher level of social development. This has led from early functionalism, the narrow interpretation of function, to an extended, wide-range functional approach, to the complex consideration of the integer system of relations inclusive of demands, requirements, and the color environment.

Of course, this functional approach itself is undergoing development, although in its germs it has been present in every stage of development throughout the history of architecture and, recently, in environment color design. Nowadays, however, it has become more conscious, unambiguous, and scientific, and it has risen to be an important factor of the up-to-date approach. The relationship between structure and function in architecture has been recognized, and this knowledge unavoidably affected environment color design. The ideas of environment color designers have to be directed by modern scientific thinking.

Activities in various areas of the built environment have become extremely differentiated. Functions have become so manifold that

categorization is not only difficult but may lead to misunderstandings. Nevertheless, functions need to be categorized; otherwise the relations between functions and colors cannot be delineated, and the role of colors in the utility function of the environment cannot be studied.

According to the activities accommodated, the environment can be divided into working spaces, community spaces, living spaces, and traffic spaces.

To demonstrate the usable function of colors in different institutions, hospitals will be dealt with in the next paragraphs. Functions of hospital buildings are very special. For some people, a hospital provides accommodation for a shorter or longer but nevertheless limited time, while for others it is a working place. Therefore, the demands of both groups have to be respected not only concerning construction and equipment but also coloration. The more so, since these demands are sometimes contradictory [2, 5, 6].

In most cases, the state of mind of a patient is *a priori* somewhat abnormal. The lonely, worried patient, so to say forcedly dragged from his habitual environment, is in need of being addressed and protectively accommodated by his new environment. On the other side, the work of the medical staff requires a great deal of concentration, and excessive color effects may distract their attention or even disturb his work. These anomalies have led to the absurd dispute among color dynamists as to whom should priority be given in the hospital ward.

In a hospital, honoring of the utility functions can be done according to different aspects. Coloration should help orientation. Applying a certain color for doors of rooms with identical or similar functions may eliminate much uncertainty. Doors not for patients may be colored so as to convey this information. Proper color design may express connections between rooms. Any obtrusive color sensation has to be avoided in examination rooms and surgeries. In bathrooms, natural color effects of the sun, sand, and water have to be mimicked. The patient finds his picture in the mirror pale and sickly if it is being colored by near strong reflections from a green surface. A similar pale-colored impression arises when the patient observes his

face neighbored by fiery orange or fiery red colors. But in rooms frequently contaminated by blood, green should be applied as complementary to red. Ward walls possibly need cheerful, warming, approaching, but not very saturated, colors. Eventual chromotherapeutic effects have to be exploited. A febrile condition in itself yearns for a cool environment. In a condition of depression, a multicolored environment has to be preferred. In a labor ward or an intensive care unit, a positively reassuring coloration has to be applied.

Aesthetic Function of Colors

Just as any work of art, every element of the environment, and the environment itself, is an inseparable unity of content and form. Just as the human environment is a space for human functions, environment elements serve somehow the realization, accomplishment, and completion of human functions, and by all that, they fulfill their own function. Thus, the human environment is up to its aesthetic function if it expresses its utility function in conformity with unity of content and form – where content is the utility function and form is the shape and color of the elements [1, 3, 5].

The essential condition of an aesthetic effect is unity between content and form, as so defined. Furthermore, the objects forming the content of the environment, or indeed the entire environment, are essentially functional. It follows that the integral expression of content can be realized by the harmonious functioning of all the components of the entire space. The practical-utility and spiritual-mental components of function are interdependent. The mental arises, and is inseparable, from practical. Now it is not realistic any longer to believe that the aesthetic form of an object or space should be possible without knowing its function. Neither is it believed that there exist universal aesthetic formulae applicable in every case nor that it is possible to force upon the environment any fine color harmony without knowledge of its function. In environment color design, it is also necessary to consider how much importance is attributed to its practical functions from the point of view of human life as a whole.

That is to say, any work and activity has its emotional, mental, and spiritual attachments. Therefore each object, tool, or space claims some of these attachments, depending on its role, importance, and function in human life.

Form becomes a necessity in the course of a “function experience,” imprinting on consciousness a harmony sensation as inseparable unity between content and form. Of course, the sight of a color complex may give aesthetic pleasure, but when separated from the content and function of the space, this pleasure is rather superficial, as it does not offer a full space sensation.

To be able to create a form expressing the message of the built environment, the designer has to be acquainted with relationships between environment structures, the so-called composition relationships, such as that of material-function-form, conditions of space effects, or the role of space-time-motion in an environment.

Informative Function of Colors

Information functions of environment serve to interpret for man the functions, the ways of utilizing, and the operation of the environment and its elements. An important part of the informative functions of the environment is expressed by color information. Depending on the message, color information may be interpreted as logic information or as artistic or aesthetic information.

Logic and aesthetic information are carried by the same elements, but a different structure belongs to every form of message. They can be characterized partly by their different visual systems, by the differentiation of their complexity and structure, and partly by the psychical differences of their messages. A message is transmitted by highlighting, contracting, and grouping some visual codes in the information-bearing surface or space while disregarding others. A group of colors attracts attention when it excels by regularity and its structure is well recognizable. Recently, the analysis of these relations has been tackled with the methods of semiotics. Although these studies mostly concerned other than visual structures, the results can also be applied to color dynamics.

Functionality of Color, Fig. 1 Safety signal colors in the CIE diagram: (a) information, (b) warning, (c) prohibition, (d) fire, (e) instruction. *N* neutral complementary domain, *Y* yellow, *O* orange, *R* red, *B* blue, *G* green

Logic information is conveyed by standard codes; they are practical and strictly mental and transmit knowledge. They prepare decisions of receivers and control their behavior and attitudes. Logic information is transmitted, e.g., by internationally agreed safety color signals. Locations of these colors in the CIE diagram are seen in Fig. 1. For instance, green means information, orange warning, red prohibition, and blue instruction. A special field of the built environment is traffic. Traffic signal colors are plotted in Fig. 2. Recently, colors indicating various technological processes have been standardized, as seen in Fig. 3. A special field of technology is the color signals of pipelines. Color signals for the fluid carried have been standardized, including different uses of the same fluid. For instance, there are different signal colors for drinking water, for utility hot water, condensing water, hot water for heating, soft water, neutralizing sewage, and other applications. In Fig. 4, pipeline colors are plotted in the given Coloroid sections [3, 4].

Color information of aesthetic content is mostly emotional. It expresses inward conditions and the wish to exert mental and emotional effects

Functionality of Color, Fig. 2 Traffic light colors in the CIE diagram: *Y* yellow, *R* red, *B* blue, *G* green, *N* neutral complementary domain

Functionality of Color, Fig. 3 Technology signal colors in the CIE diagram: *Y* yellows, *OR* orange reds, *B* purples and violets, *BG* bluish greens, *N* neutral complementary

based on a common semantic knowledge. Because of their operative and recording functions, visual codes are not only carriers of the message, and social ideas of the color-designed space as a work of art, but may also display the

attitude typical of the artistic subject and culture. It follows from all these that color dynamics creates complex color conditions and puts them into a colored world; thereby it has a manifold message, that is, it both expresses and molds human consciousness and emotions. In other words, environment color design is an artistic activity on a large scale, a piece of art existing in the built space, and as such, it has not only to cope with its specific iconic task but also to meet the special conditions of color dynamics.

Functionality in Architectural Color

Color is essential to the appearance of architecture and, therefore, impacts on the visual outcome of the built environment. Encompassing the practical and aesthetic aspects of architecture, the colors of building exteriors generate physical and emotional effects on users, and in addition, serve as means of expression. For its breadth of implications, architectural colors, which once were simple to resolve, these days may be considered a matter for experts.

Before taking color decisions for building exteriors, orientation and climate should be observed, especially when critical conditions of visibility and reflectivity occur. Color, as a primary perception, produces physiological effects on humans. Because of the surface extensions involved, architectural colors are relevant to ergonomics, specifically concerning visual comfort. For instance, color may be used to compensate the glare produced by large vertical areas in environments of high luminosity.

The physical properties of color account for energy conservation and thermal comfort in buildings, complementing design principles of orientation, insulation, and ventilation. Following these criteria, light colors and reflective materials are used to diminish the overheating of roofs in hot climates, whereas opaque black surfaces seek to absorb maximum heat. Besides solar radiation, the outermost layer of a building should withstand rain, humidity, dust, and contamination. Durability and maintenance are important considerations for deciding exterior colors, as cladding and

Functionality of Color,

Fig. 4 Signal colors (*S*) to distinguish pipelines in Coloroid sections. The horizontal axis shows the Coloroid saturation scale, the vertical axis, and the Coloroid lightness scale. Numbers represent Coloroid hues

painting materials come in colors which age differently.

Apart from the practical aspect, color on buildings exerts power at different levels of cognition with impact on the user's emotional well-being. Clarity of perception, orientation, understanding of general and specific information, appreciation of beauty and place identity are only some of the advantages that may be experienced through architectural colors in this respect.

From the User's Perspective

Colors may be used on façades and exposed structures in pursuit of specific intentions of owners, architects, and authorities. Image, which refers to the character of a building within its context, is usually prioritized when selecting colors for exteriors. Color is often used as a means of decoration, serving aesthetic purposes but also acting as a reference to ownership, identity, and content.

Architectural colors may allude to a symbolic aspect, as hues convey meaning. Using this as a resource, the chromatic composition of a building may attract attention for personal or commercial

interests. For instance, corporate identity and affiliation may be represented on a façade by replicating colors associated with a certain brand or institution.

Codification applied to façade colors may also contribute to orientation, as distinctive tones and combinations are perceived in the distance. In this way the role of a building is anticipated by its external colors, provided that these are in accordance with its use. As an example, the colors of a day-care center give a clear idea that it is directed towards children.

On a broader scale, familiarization with large areas such as residential developments and commercial centers may be clarified through color design. On the other hand, in areas that conserve features of natural and cultural value, it is important to respect color as an element of identity [7], for it grants uniqueness and sense of permanence to places.

Building exteriors act as a backdrop to human activities, especially in cities where scale and monotony are not welcoming. Colors on façades promote visual interaction with the surroundings and also present an opportunity to enhance outdoor spaces. As a component of the public realm,

these are exposed to acceptance or rejection from the public. By maintaining a balance between consistency and variety, tradition and renovation, and beauty and fun, the aesthetic aspect of architectural color becomes relevant in the development of a positive attitude and a sense of belonging in the user.

From an Architectural Perspective

The spatial and material characteristics of a building provide the support for architectural color. Color and light determine the perception of three-dimensional form, affecting the appreciation of distance, size, and definition of planes in a way that the building and its color produce an integral result, as a sculptural object.

The colors of buildings may be the outcome of constructive processes, as usually happens with exposed construction materials. Nowadays a variety of industrial products for exterior cladding is offered in specific color palettes, or customized, as in the case of paint finishes. Anyhow, to accomplish the various functions of color in architecture, and meet the requirements of each project in the semantic, formal, and contextual aspects, an understanding of color properties and of the relevant cultural codes is necessary.

As regards the building's image, enhancement is a desirable objective. Color may reinforce its style and design concept. In this way, an edifice of architectural or historical value may recover its authenticity by color restoration. Addressing the parts of a building with colors that suit the actual function of the building is a straightforward approach to color design. Otherwise, existing constructions may be transformed to convenience through plain colors and textures, or else, by the application of pictorial techniques such as supergraphics [8], trompe l'oeil, and camouflage. However, the preservation of the architectural character is conditioned to the appropriateness of color design and the particularities of each case.

On a broader context, by the use of color, it is possible to modify the relation of hierarchy, proximity, and perceived area among buildings and its connection to the setting. In urban and natural

environments, color has the potential to regulate the impact of obtrusive structures. More so, when inserting a new building in an existing network, a mindful color proposal is required. Color may be applied to buildings by using principles of attachment and detachment [8], seeking color effects similar to those of the surroundings with the purpose of integrating the constructions to the panorama, or else, to turn them into landmarks, by color differentiation.

Color applied to architecture offers countless possibilities. These should be carefully studied, selected, and refined. For the sake of places, in the best interest of the user and to avoid color pollution, architectural color should be handled in a knowledgeable way.

Color Tectonics in Architecture

Tectonics in architecture and urban design is the discipline dealing with the principles of design, structure, construction, and ornamentation. Color tectonics refers to the function that color plays in accentuating these principles.

Color and form are codependent in built form. In architecture color plays many roles throughout the design process. Color is used dynamically in diagrams in the conceptual phase. In the design development phase, color can enhance the perception of physical form and define interior space. In detailing color can express the parts of the building that contribute to the whole. These color and form strategies will be present as material color in the finished building. In the architecture, color can be functional as an enhancement to form or abstract as expressive media. Color can be associative by carrying cultural values and meaning, as well as eliciting emotional response. In all cases color combined with form becomes another layer of interpretation and clarification of the intentions of the designer [8].

Conceptual Phase

A building, like a city, has an order based upon a clear hierarchical relationship of parts to the

Functionality of Color,
Fig. 5 Color adding
 nuance to a concept
 diagram by Louis Kahn

F

whole. Architecture begins with a concept expressed both verbally and in diagram. In the conceptual phase of the design process, line drawings are used to represent an abstract relationship of the essential parts of the building. These parts can be described metaphorically or formally, and the relationship of these parts to one another creates the generative idea that is the point of departure for the design. These relationships are often expressed as a dialogue between oppositions such as public/private or active/passive. They can also represent events in the experience of architecture such as hierarchy, separation, connection, transition, and assimilation. The drawings are usually monochromatic, but if one assigns colors to these diagrams representing the character of the part (i.e., red represents active functions and blue passive, or saturated hues might be dominant and muted hues subordinate), then color juxtaposition and contrasts can set up a more visually dynamic relationship of these parts in the diagram. These color choices in the conceptual phase are chosen for their dynamic relationships in juxtaposition rather than by functional criteria, but these colors will often influence choices in the design development phase such as the delineation of three-dimensional form, building materials, and lighting.

A repertory theater is a place where actors must project their voice to the audience without

acoustical support. A design concept for a repertory theater by Louis Kahn was first expressed metaphorically as “a violin within a violin case.” The diagram was a box representing the outer shell of the building or the “violin case” with an irregular form inside representing the “violin,” an acoustically designed theater. In black and white, this is just a simple diagram. With color, however, the violin and violin case form an expressive dialogue between these parts, making them more dynamic and meaningful (Fig. 5).

Design Development

In the design development phase of a design process, color is used to accentuate or diminish three-dimensional form. The exploration of perceptual effects created by color, particularly the spatial effect of color, color and atmosphere, and the familiarity with the principles of camouflage [9] are helpful tools in this pursuit (Fig. 6). The color decisions here are based on how the eye perceives color and form. The accentuating and disguising of form with color are the techniques supporting color tectonics. Using color in models in this phase establishes color juxtapositions and contrasts that will be present in the final building. Model studies similar to the experiments by Lois Swinoff [10] are valuable exercises.

Functionality of Color,

Fig. 6 Transforming two solid cubes and a void with a color illusion

**Functionality of Color,**

Fig. 7 Color used for “deconstruction.” (Portland Building by Michael Graves, Portland, Oregon)

The purpose of color tectonics is to use color to clarify and enhance the perception of building form. This form is made up of parts arranged hierarchically that unite to shape the whole. This color/form carries the aesthetic and expressive intentions of the architect, and clarity of expression is usually the goal. In some instances, however, there is an intention to disguise and actually deconstruct the true form, and color becomes a powerful tool in this endeavor. This was the case

in the Portland Building during the period known as deconstruction in architecture (Fig. 7).

Detail

The details of buildings carry expressive content. Structural details communicate what elements in the building are supporting and load bearing and what are non-load bearing and serve to enclose the

Functionality of Color, Fig. 8 Color contrast emphasizing structural detail. (The Arts United Center by Louis Kahn, Fort Wayne, Indiana)

building and define space within it. Many functional parts of a building are repetitive, and through this repetition patterns and rhythms are established which support the unity of the building as a whole. Color contrasts provide a powerful tool for making these parts visible in a meaningful way. In the main entry facade to the Fort Wayne Repertory Theater, light gray concrete is contrasted with darker brick to both characterize the structural forces within a large wall and to accentuate the main entry (Fig. 8).

Color Imagery

In the final or building phase of the design process, color choices are more specific. To this point, color has been an integral tool in clarifying the conceptual and design intentions of the architect and not as a secondary consideration in the design process. The final color/form imagery will both convey these intentions and also carry

meaning through cultural associations, symbolism, and emotional response. The use of colors from the natural and built environmental contexts can give the architecture a sense of place as well [11]. In this process color is a principal consideration through all phases. The imagery experienced in the architecture will carry these design ideas in form and structure through perceptual color effects, but there will be an additional layer of meaning with the associative uses of color and the aesthetic imagery from experiencing the architecture as a whole in its environmental context.

Galaxy Color Magnitude Diagram

Michael H. Brill
Datacolor, Lawrenceville, NJ, USA

Definition

A scatter graph of galaxies showing the relationship between each galaxy's absolute magnitude and its estimated temperature, or between optical and perceptual proxies for these quantities. The construction of such a diagram is similar to that of the Hertzsprung-Russell diagram, but the interpretation in terms of physical properties is not as precise.

Absolute Magnitude and Temperature Scales

To compute a galaxy's absolute magnitude, it is treated as a point-like object, whereupon its radiation is corrected (by the inverse-square law) to a distance of 10 pc, and the absolute magnitude is computed as the number of $10^{-0.4}$ attenuations of similarly compensated power from a reference to achieve a match.

The temperature is also the same "effective temperature" as is used in the H-R diagram. However, galaxies are visible from much farther away than individual stars, so a galaxy's recessional redshift

exerts an appreciable influence on its effective temperature. Because light from farther galaxies (and greater redshift) requires more time for light to travel to the Earth, the galaxy color-magnitude diagram, if it were not redshift corrected, would depict an earlier universe at the red end of the temperature scale. However, in practice the temperature is redshift corrected to be in the "rest frame" of the galaxy. In this case, the galaxies divide into two clusters: bright and reddish as opposed to dim and bluish. The existence of such clusters places strong constraints on theories of galactic formation.

History

Galaxy color-magnitude diagrams came into wide use starting in 1990, when the Hubble Space Telescope was launched into orbit. The Space Telescope was able to render high-contrast images outside the Earth's atmosphere without encountering the absorption, scattering, and haze that beset Earth-bound telescopes. In digital images conveyed to earth from the Space Telescope, it was possible to see the colors, not only of stars, but of whole galaxies that are so distant as to be too dim to measure on the Earth.

Coordinate Options

Color-magnitude diagrams are not always defined in terms of fundamental physical properties such as

those described above. In one embodiment, the galaxy color-magnitude diagram coordinates are defined by the log outputs of two sensors, typically called *g* and *r*, the sensors having different spectral sensitivities. The abscissa records *r* (which stands in lieu of the absolute magnitude), and the ordinate records *g*–*r* (which relates to the temperature). At the top of the diagram, one finds the red sequence of galaxies (elliptical galaxies), and at the bottom, one finds the blue cloud (spiral galaxies).

Gamut Volume

Philipp Urban

Fraunhofer Institute for Computer Graphics
Research IGD, Technische Universität Darmstadt,
Darmstadt, Germany

Synonyms

CIECAM02 (Standards: CIE); CIELAB
(Standards: CIE)

Definition

The gamut volume describes how much of a color space a gamut occupies. Hence, it depends on the color space in which the gamut is represented. In order to be used as a meaningful quantity to compare gamuts, a representation within a highly perceptually uniform color space is recommended. Color spaces typically used to calculate gamut volumes are CIELAB or CIECAM02 [1]. Please note that these spaces are only nearly perceptually uniform. Hence, spaces with improved uniformity [2, 3] are sometimes used as well mathematically; the gamut volume V is defined by the volume integral

$$V = \iiint_G dc_1 dc_2 dc_3,$$

where G is the gamut, and c_i are the color space coordinates, e.g., $(c_1, c_2, c_3) = (L^*, a^*, b^*)$. The gamut volume is expressed in *cubic color space units* and mostly rounded to thousands for device and media gamuts [4].

In a perceptually uniform color space, the gamut volume is nearly monotonically related to the number of distinguishable colors within the gamut, i.e., the larger the gamut volume, the larger is the number of distinguishable colors in the gamut. Mathematically, the number of distinguishable colors n within the gamut may be expressed as the smallest number of just noticeable distance (JND) spheres covering the gamut, i.e.,

$$n = \min \left\{ |\mathbb{S}| \mid G \subset \bigcup_{S \in \mathbb{S}} S \right\},$$

where G is the gamut, $\mathbb{S}$ is a set of JND spheres, and $|\mathbb{S}|$ are the number of elements in $\mathbb{S}$. It is worthy to mention that the JND depends on the viewing condition, i.e., the luminance level, viewing field, adaptation state, etc. Hence, the gamut volume and the number of distinguishable colors within the gamut are not two sides of the same coin. However, assuming similar viewing conditions, gamut volumes can be reasonably compared to determine the gamut that includes more distinguishable colors.

The gamut volume is only one quantity to compare gamuts and does not give any information about colors covered by the gamut. A gamut that includes highly relevant colors for a distinct application should be preferred over a gamut that does not cover these colors regardless of the gamut volume.

Calculation

A major problem of accurately calculating the gamut volume is the non-convex shape of the gamut within a perceptually uniform color space. For output devices, such as printers, displays, or

projectors, a good approximation of the gamut is given implicitly by an accurate device model

$$\mathcal{M} : P \rightarrow C,$$

i.e., a predicting function that maps the control value space P (e.g., $P = \text{RGB}$, CMY) into the color space C used for gamut representation (e.g., $C = \text{CIELAB}$, CIECAM02 , etc.). The gamut G can be parametrized by the device's control values, i.e., $G = \mathcal{M}(P)$. Using this parametrization and assuming that $\mathcal{M}$ is an injective differentiable function with continuous partial derivatives, the gamut volume can be computed using the substitution rule for integration

$$\begin{aligned} V &= \iiint_{G=\mathcal{M}(P)} dc_1 \, dc_2 \, dc_3 \\ &= \iiint_P |\det(J\mathcal{M}(p_1, p_2, p_3))| dp_1 \, dp_2 \, dp_3, \end{aligned}$$

where $J\mathcal{M}$ is the Jacobian matrix of $\mathcal{M}$. Since P has typically cubic shape, the latter integral can easily be calculated numerically. Furthermore, no representation of the rather complex gamut boundaries within C is required.

While mathematically elegant this method is often inapplicable, e.g., for image gamuts or if the control value space of a device has more than three dimensions, such as for multi-ink printers (CMYK, CMYKOG, etc.). In this case, a gamut boundary descriptor (GBD) [5] describing the gamut boundary by a tessellation within C can be utilized. This tessellation is then used as the boundary of a tetrahedralization that fills the entire interior of the gamut. In most well-behaved cases, tetrahedralization can be simply generated by forming tetrahedra with each of the surface triangles and one inner point, e.g., the centroid of the GBD vertices [4]. To approximate the gamut volume, the volumes of all tetrahedrons within the tetrahedralization are added up. The volume of a tetrahedron with vertices a , b , c and d is given by $1/6|\det(-a - b, b - c, c - d)|$. For devices using additive

color mixture, such as displays, the gamut is convex in the CIEXYZ color space. A tetrahedralization of the gamut in CIEXYZ space allows a convenient partitioning into sub-gamuts for further consideration. Since a transformation,

$$\mathcal{F} : \text{CIEXYZ} \rightarrow C,$$

from CIEXYZ into a perceptually uniform color space C can be assumed to be a diffeomorphism, the following equation applies:

$$G = \bigcup_{T \in \mathbb{T}} \mathcal{F}(T),$$

where G is the gamut in C , and $\mathbb{T}$ is the set of all tetrahedrons within the tetrahedralization. Hence, the gamut volume can be computed as follows [6]:

$$\begin{aligned} V &= \iiint_G dc_1 \, dc_2 \, dc_3 \\ &= \sum_{T \in \mathbb{T}} \iiint_{\mathcal{F}(T)} dc_1 \, dc_2 \, dc_3 \\ &= \sum_{T \in \mathbb{T}} \iiint_T |\det(J\mathcal{F}(X, Y, Z))| dXdYdZ, \end{aligned}$$

where $J\mathcal{F}$ denotes the Jacobian matrix of $\mathcal{F}$. It should be noted that the meaningfulness of the computed gamut volume – with respect to its relation to the number of distinguishable colors – is usually more effected by the uniformity of the color space C rather than by the computational method.

Applications

Most often gamut volumes are used to compare imaging systems with each other or with standard gamuts (e.g., sRGB or Adobe RGB). Also the volume of gamut intersections is used and related to standard gamuts, e.g., to state that a display's gamut covers more than 95% of the Adobe RGB gamut.

The gamut volume is sometimes used as an objective function to optimize imaging systems (e.g., displays or printers). Particularly, the spectral or colorimetric characteristics of printing inks or display primaries are optimized to maximize the gamut volume. Most of such optimizations are subjected to other beneficial properties of imaging system or feasibility constraints.

Ganglion Cells

Arne Valberg¹ and Jan Kremers²

¹Department of Physics, Norwegian University of Science and Technology, Trondheim, Norway

²Department of Ophthalmology, University Hospital Erlangen, Erlangen, Germany

Definition

Retinal ganglion cells are the first real neurons in the visual system, and they transmit the visual information to the brain. The retina processes the visual signals, and they determine the response properties of the retinal ganglion cells and the constraints for color vision.

Physiology of Retinal Ganglion Cells

This entry is only concerned with primate retinal ganglion cells. The morphology and physiology of ganglion cells in other mammals and vertebrates may be quite distinct. Trichromatic theories of color mixture have had a tendency to over-emphasize the role that L-, M-, and S-cone receptors have for color *perception*. The realization, however, that these physiological units can only explain the laws of additive color mixture and color matching (metamerism) has led to an end of this bias. Modern cone-opponent color vision models assume antagonistic inputs of two or more cone types to the receptive field of retinal ganglion cells (e.g., +L-center –M-surround, giving an “L–M” ON-center cell, or an +M-center–L-surround, “M–L” ON-center cell; also called increment cell). The opposite configuration is found in “–L + M” and “–M + L” OFF-center cells (decrement cells). Ganglion cells with S-cone inputs can be characterized as “M–(S + M)” and “S–(L + M)” cells [1–5]. This organization is partially combined with spatial antagonisms of the receptive field centers and surrounds. The idea of parallel pathways has moved the scientific interest from the ancient idea of cones as color units toward retinal ganglion cells as the basis of color vision.

Retinal ganglion cells are situated near the inner surface of the retina. They receive cone signals modified by horizontal, bipolar, and amacrine cells. In the ganglion cells slow, standing potentials of the cones and bipolar cells are transformed into a series of nerve impulses (spikes). Spikes are “all or none” electrical signals of about 1 ms duration each. The number of spikes per second is used as code for transmitting information. Excitation of a cell results in an increased firing frequency, whereas inhibition results in a reduced rate of firing. The number of spikes of a particular cell contains information about the intensity or strength of a visual stimulus. Information about a stimulus’ compound features such as contrast, form, color, movement, direction of motion, distance, etc. is conveyed by activation of more or less specialized cell types.

Retinal ganglion cells have long axons extending into different brain areas. The projection to the lateral geniculate nucleus (LGN) and from there to the various visual centers of the brain is the main pathway that is responsible for conscious visual perception. Ganglion cells are spiking neurons of different sizes, connections, and spectral selectivity. There are about 1.5 million different retinal ganglion cells in the human retina, each type forming a mosaic of receptive fields with a close to ideal covering factor (neighboring dendritic fields do not overlap [6]).

Two major types of ganglion cells carry cone opponent information and are the physiological basis of color vision. Midget retinal ganglion cells are connected in an opponent way to L- and M-cones and have rather small dendritic fields. In the central fovea, the receptive center of a single midget ganglion cell is connected to a single cone. They project to the parvocellular layers of the LGN. It is unclear if the receptive surrounds and the centers of peripheral cells are also cone selective or if they receive mixed cone inputs. With mixed inputs, the cone opponency would mainly originate in the single cone input (for foveal cells) or in a biased input (for peripheral cells) in the receptive field center [7].

Cells making contact with S-cones (the so-called bistratified cells [8] projecting to koniocellular LGN cells) do this in two different synaptic layers and seem to have a coinciding (coextensive) center/surround structure of their receptive fields. Parvocellular (PC)- and koniocellular (KC)-ganglion cells (about 80% of all retinal ganglion cells) have a sustained firing pattern.

In addition to the cone-opponent retinal ganglion cells, the transiently responding, spectrally nonselective magnocellular (MC) or parasol ganglion cells comprise about 10% of all retinal ganglion cells. These contrast-sensitive cells have spectral sensitivities matching the psychophysically determined spectral luminosity function $V(\lambda)$ to luminance contrast. They combine L- and M-cones in an additive way ($L + M$) in both center

and surround of their receptive field. MC-cells also form parallel sub-pathways as they are either of the ON-center, OFF-surround, or OFF-center, ON-surround types. Since these cells have $V(\lambda)$ -like spectral sensitivities and large receptive fields, they are excellent candidates as neural substrates for minimally distinct border (MDB) and heterochromatic flicker-photometric luminance [3].

A relatively small number of retinal ganglion cells are internally photosensitive with their own photopigment, melanopsin, and contribute to the circadian rhythm and pupillary light reflex but little to vision [9]. Recent studies indicate that they may have limited influence on vision including color vision [10].

A particular color percept, say orange of medium lightness, may result in activation and/or inhibition of multiple cell types. The perception and scaling of lightness, for example, may be a result of interaction between nerve processes that are elicited by light increments and light decrements in parallel (increment- and decrement channels) [11]. Equal responses of a low-level cell such as a certain polarization of a cone receptor's potential or the number of nerve impulses/s of a retinal ganglion cell may result from exposure to several different stimuli, such as changes in color, intensity, size, orientation, or combinations of these. The combination of visual attributes that makes up a complex visual object can be regarded as a result of integration, correlation, and comparisons of these lower units' activities. Retinal ganglion cells project via the LGN to specific visual centers of the brain, depending on the "trigger features" they encode.

Ganzfeld

Suncica Zdravkovic
Department of Psychology, University of Novi
Sad, Novi Sad, Serbia

Definition

A ganzfeld (a German word for “whole field”) is obtained when an observer is exposed to an absolutely homogeneous stimulation that covers the

entire visual field. Any particular wavelength or intensity can produce the same effect.

History

The ganzfeld was first introduced in 1930 [1], by German Gestalt psychologist Wolfgang Metzger (1899–1979). Metzger was interested in elementary visual phenomena produced by impoverished visual conditions. The ganzfeld contains no luminance border, luminance ramp, or texture, while the light reaching the eyes is equal from all possible directions. Such conditions, called whiteout, can occur naturally during a snowstorm or in an airplane flying through clouds.

Perceptual Experience in the Ganzfeld

The typical visual phenomenology, for a person of normal sight, includes the emergence of “Eigen-grau” [2], a uniform gray fog of indeterminate depth. This percept occurs regardless of the physical intensity and wavelength of the ganzfeld. Any color in a ganzfeld will eventually fade to filmy gray. The experience of a bright ganzfeld differs from that of a completely dark ganzfeld. Total darkness implies a lack of visual objects and is somewhat less disorienting. However, disorientation in a bright ganzfeld is fast and compelling.

From the beginning, the observer is unable to fixate any part of the field and becomes conscious of the vitreous opacities and blood vessels within the eye. Perceived luminance gradually decreases, the whole field slowly decolorizes, turning into a gray fog. This fog sometimes has a barely noticeable washed-out tone complementary to its actual color [3].

Prolonged exposure to a ganzfeld results in more complex percepts. Occasionally even patterns (dots, lines) are reported. Because hallucinations have been reported in extreme cases, the method has been used outside of vision science. Sometimes prolonged exposure (10–20 min) leads to intermittent losses of vision (so-called “blank-out”) and sometimes participants cannot even report if their eyes are open or closed [3].

In traditional studies, phenomenological reports were obtained from observers trained in providing such introspective reports “post hoc” from memory [3]. The extent of this introspection is debatable, especially in the case of complex visual experience. This constitutes a problem for a phenomenon that might involve disorientation and consciousness-altering states. Alternative methods include “on-demand” reports either elicited by the experimenter or volunteered by the observer. This allows a random sample of momentarily experienced states with no involvement of memory [3]. Unfortunately, some of the same criticisms are applicable here, too. This method also requires training in introspection.

Producing an Experimental Ganzfeld

Although a primitive ganzfeld can be achieved by placing a person in complete darkness, creating a proper ganzfeld of the desired brightness is not a trivial challenge.

In the 1930s, observers were placed in front of either a smooth, homogeneous wall (Fig. 1a) or a large sheet of paper [1, 3]. A simple way to create a ganzfeld is to cover each eye with a section of a table tennis ball (Fig. 1c) [3]. These need to be trimmed to fit the shape of the face surrounding the eye, leaving no extra gaps for illumination to leak in, and they can be attached to the face using cosmetic cement. Industrial production does not guarantee an utterly uniform thickness of the

Ganzfeld, Fig. 1 Traditional spatial arrangements of Ganzfeld [3]. (a) Observer in Metzger’s experiments was placed in front of a uniform wall lit from behind. (b)

Domes lit from outside. (c) Lenses or table tennis balls placed in front of the eyes functioning as light diffusers

plastic, but this is not a problem because the surface is too close to the eye for focus. Another option is placing the head inside a large hemisphere, which is uniformly illuminated from outside (Fig. 1b). A somewhat better solution is the use of translucent contact lenses. This method provides a high degree of homogeneity.

More modern studies tend to use “computer-controlled xenon lamp-based D-ILA projector” creating (usually red) ganzfeld [3, p. 1366].

Finally, any change in luminance or color, including blinking, restores perception. Given that the ganzfeld effect can be achieved fast, this is not necessarily a problem. If prolonged viewing is required, the eyelids can be taped open to prevent blinking, but the eyeballs need to be kept moist. This is easily achieved if the eye is completely covered by the table tennis ball section, as described.

Theoretical Importance

The ganzfeld demonstrates that our senses in general (vision in particular) function to detect change. Invariant stimulation does not produce a sensory response. Framed in Gestalt terminology, an unstructured physical field cannot produce perception due to the lack of perceptual organization.

Observable Characteristics

Brightness. The full ganzfeld phenomenon is achieved on average after 5–7 min [4]. During that time, with no change in stimulation, perceived brightness slowly decreases until it reaches the final value.

If the luminance in a ganzfeld is subjected to subliminal changes over time and space, observers can still detect the correct direction of change [5]. For a completely homogenous ganzfeld (9.1 footlambert), changing 1000-fold per hour at a constant rate, observers detected the direction after 9.7 min.

Wavelength [6]. Although the ganzfeld produces an achromatic, dark gray percept, irrespective of original conditions, the initial

wavelength still dictates some characteristics. Longer wavelengths fade faster than short wavelengths. Shorter wavelengths create an additional sensation of field darkening.

Monocular versus binocular ganzfeld. It has been shown that a ganzfeld presented binocularly (i.e., viewed with two eyes) does not show a loss of visual perception (so-called “blank-out”) typical for monocular viewing [7]. However, recent findings show that a gradual loss of brightness and saturation (so-called “fade-out”) is measurable both for monocular and binocular ganzfeld. Fade-out is however determined by the original field intensity and wavelength [8].

Sex differences [9]. Female observers are more responsive to longer wavelengths. They also preserve visual sensation shorter and report a fewer “blank-out” effects than male observers.

Explanation

The patterns that appear during the short ganzfeld exposures, such as zigzag lines or dot fields, are usually explained by early retinal processes [3]. Receptive and other retinal cells exhibit spontaneous activity, oversaturation, and inhibitory reactions. Prolonged exposure elicits complex percepts, which presumably involves the central nervous system. The loss of vision is probably the consequence of brain discarding uninformative visual input about invariant stimulation.

There is a correlation between “blank-outs” and alpha activity in the resting EEG [10]. Alpha activity (8–12 Hz) is otherwise typical for relaxed states with no stimulation and closed eyes.

Related Phenomena

Aftereffects. If the ganzfeld is induced by yellow table tennis balls, after their removal the world will tend to look bluish, due to chromatic adaptation. Also during the initial bleaching of the original ganzfeld color, sometimes the percept does not remain neutral but adopts a pale complementary color.

Artificial scotomata. Eye movements can be counterfeited by fixating a large portion of the visual field to stimulate an identical part of the retina. This leads to “fade-out” and loss of percept within seconds. To maintain normal perception, a constant change of stimulation is necessary and this is achieved by eye movements. The absence of eye movements in large areas of the visual field, known as artificial scotomata, leads to perceptual filling in, creating large uniform surfaces.

Sensory deprivation. Although the ganzfeld is exceptionally impoverished stimulation, the phenomenon represents perceptual but not sensory deprivation. In the former case, we have simply unstructured stimulation, while in the latter, stimulus’ intensity is extremely reduced.

Dark field vision. When observers are placed in total darkness in a relaxed state, with the eyes closed, they often report the appearance of phosphenes, believed to be the consequence of spontaneous firing of the cells [3]. Phosphenes are similar to the percepts in the early stages of ganzfeld exposures.

Global Illumination

Tobias Ritschel
Department of Computer Graphics, MPI
Informatik, Saarbrücken, Germany

Synonyms

Color bleeding; Indirect illumination;
Interreflection; Light bounces

Definition

Global illumination (GI) is illumination reflected more than once inside a scene.

Introduction

After light was emitted, it has to be reflected before it can arrive at the eye of an observer or a sensor. When this reflection occurs once, it is called local or direct illumination. Illumination which has been reflected more than once is referred to as global or indirect illumination (GI). Reflection of light is sometimes called a bounce. If light is reflected two times from a surface, it is called the one-bounce indirect illumination; if it is reflected three times, it is called two-bounce; etc. As physical reflectance is below one, only a finite number of bounces contribute to the scene illumination.

Example

A simple example of GI is best visible when putting a rectangular achromatic cardboard next to a perpendicular chromatic (e.g., red) piece of cardboard. When directional light is cast perpendicular onto the red cardboard (and consequently no light is cast on the achromatic cardboard), the white cardboard is still illuminated due to the indirect and colored (reddish) light from the chromatic (red) cardboard.

Phenomena

Depending on the reflective properties of the surfaces, GI can create different visual phenomena. For Lambertian surfaces (such as the aforementioned cardboard), light is reflected in all directions equally following a cosine distribution. For specular (mirrorlike) surfaces, light is distributed more in directions similar to the mirror direction (a Dirac distribution). The resulting concentration of light on the receiver side is called a caustic.

GI is subject to similar principles that govern local illumination: if a surface blocks the line of sight between a surface point A and another surface point B, no light is exchanged between A and B, and B is said to lie in A's indirect shadow. In the same way, a mirror can reflect indirect light as well as it can be refracted.

Strictly speaking, multiple reflections or refractions are also GI. However, the term GI is mostly used if the reflection is a true convolution that accounts for multiple directions and not only a single refracted or reflected one. At the same time, lighting from extended (area) light sources, such as the sky, is sometimes referred to as GI as well.

GI tends to be more colorful than local illumination, as light is filtered at every reflection, which is never perfectly white. This contributes to the color mood of a scene but can also be a difficulty, e.g., in white balancing where the illuminant is complicated.

Global illumination is present also in scenes without hard surfaces but participating media. Here, local illumination corresponds to single scattering, and global illumination corresponds to multiple scattering.

Formalization

Conceptually, linking all points where light is reflected results in a light path; the process of illumination along such a path is called light transport. The vertices of the light path can be labeled according to the type of reflection occurring. The light vertex is denoted as L , a diffuse reflection as D , a specular reflection as S , and the eye as E . As an example of this notation, "LDE" describes light that was emitted from the light and bounced diffusely once before arriving at the eye; "LDDE"

denotes one indirect diffuse bounce, “LDSE” the reflection of a diffuse surface, and “LSDE” a caustic.

The rendering equation [1] is a formal way to describe global illumination. It defines the radiance L_o leaving a differential surface element at location $\mathbf{x}$ with normal $n(\mathbf{x})$ in direction ω as

$$L_o(\mathbf{x}, \omega_o) = L_e(\mathbf{x}, \omega_o) + \int_{\Omega} L_i(\mathbf{x}, \omega_i) f_r(\mathbf{x}, \omega_i, \omega_o) < n(\mathbf{x}) \cdot \omega_i >^+ d\omega_i$$

where L_e is the radiance emitted at location $\mathbf{x}$ in direction ω , Ω is the space of directions in the upper hemisphere above $\mathbf{x}$, L_i is the incoming light arriving at $\mathbf{x}$ from direction ω , f_r is the bi-directional reflectance distribution function (BRDF) which is the ratio outgoing radiance and incoming irradiance, and $< \cdot >^+$ is a dot product that is clamped at zero.

The difficulty of solving this equation is due to the fact that the incoming light and outgoing light appear on both sides of the equation. Solving the equation for a given scene means to find L such that the equation holds.

Computation

For computer graphics, GI is more challenging to compute than local illumination. Including GI in image synthesis leads to more realistic and visually appealing results. The color mood in a scene is to a large extent related to GI. Several approaches exist to compute it.

The most general approach is Monte Carlo ray tracing: For every pixel multiple rays that model geometric optics are intersected with the scene [2]. Whenever a ray hits a scene surface, it is continued in a random direction. After a number of hits, the iteration is stopped, and local as well as global illumination is accumulated according to the combined reflection properties at the hit positions and the local illumination at the last hit. This procedure can simulate all light effects but takes long to compute or results in noisy images.

Radiosity takes a different approach and discretizes the scene surface into finite elements and simulates the energy exchange between them by solving a system of equations [3]. Its basic principle is the form factor that describes the light arriving at element A from element B. Radiosity is best at simulating diffuse indirect illumination but can be extended to specular light transport. It does not scale well to large scenes or highly specular materials.

If only very few paths from the light illuminate a location, it will appear noisy using Monte Carlo ray tracing. As a solution, instead of starting light paths at the eye, they can be started at the light source in a process called light tracing.

When paths are started from both the eye and the light and end points of sub-paths are connected, the procedure is called bi-directional path racing [4].

For notoriously difficult light paths, where only a low percentage of all possible paths contribute a lot of energy to an image, the solution to the rendering equation can be found using Metropolis light transport sampling [5]. The approach generates random light paths, which are changed (mutated) such that more relevant paths are explored in greater detail than less relevant paths.

At third alternative is photon mapping [6]. It is performed in two passes. The first one is similar to light tracing but stores the hit locations into a spatial data structure (the photon map). In the second path, rays are traced from the eye, but every time a surface is hit, the illumination is constructed from the local density of photons inside the photon map. Photon mapping is the best established method to render caustics.

Several approximate approaches to compute GI exist. Instant radiosity [7] approximates the indirect lighting using a high number of virtual point lights. Lightcuts [8] is an approach to compute GI from the high number of virtual point light in sublinear time. GI rendering at interactive frame rates can be achieved using graphics hardware [9].

If GI is due to extended light sources, and not due to multiple bounces, Image-based lighting (IBL) is applicable [10]. Here, the light entering a scene from a direction is stored into every pixel of a (high dynamic range) spherical raster image. To use this image for rendering, it is preprocessed once and can later be used to compute illumination easily.

A simplified version of GI is ambient occlusion (AO) [11]. AO is the special case of illumination by a constantly white, infinitely extended directional area light source. The resulting illumination is similar to the one found on a cloudy day and contains only directionless and soft shadows.

Synonyms

[Glossmeter](#)

Definition

A gloss meter is an instrument that is used to measure specular reflection gloss of a surface. Gloss is determined by projecting a beam of light of intensity at a fixed angle onto a surface and measuring the amount of reflected light at an equal but opposite angle.

Introduction

The gloss meter measures gloss intensity under a fixed set of illumination and viewing conditions [1–3]. Figure 1 illustrates the configuration of the collimated light illumination source and the filtered detector across a limited range of observation reception angles. The measurement results of a gloss meter are related to the amount of reflected light from a black glass standard with a defined refractive index. The ratio between the reflected and incident light for the specimen across a range of angles is compared with the ratio for the gloss standard, is recorded as gloss units (GU).

Applications

There are a number of different geometries available for gloss measurement, according to types of the specimen surface to be measured. For non-metals such as coatings and plastics, the amount

Gloss Meter, Fig. 1 (a) Schematic diagram of gloss measurement and (b) gloss meter

of reflected light increases with a greater angle of illumination, as some of the light penetrates into or is reflected from the surface, which is absorbed or scattered in the material depending on its compositions. Metals have a much higher reflection and are therefore less angularly dependent.

Many international or national standards are available according to different types of gloss and materials such as paint, ceramics, paper, metals, plastics, and so on. For example, ISO 2813 specifies measurements of specular gloss in the paint industry. Many industries use specific gloss meters for their quality control works to ensure consistency in the manufacturing processes. The gloss meter is widely used in the automotive industry, with applications extending from the factory floor to the repair shop.

In the case of transparent materials, the gloss readings can be increased up to 2000 GU due to multiple reflections in the bulk of the material. For these applications, it is common to report the measurement results in percentage reflection against the incident light. For each application, the types of gloss meter and their operation procedures must be strictly specified for intercomparisons. Of the above, the angle of illumination is of most importance. Table 1 defines the measuring angle depending upon three kinds of the different surface characteristics: matte, glossy, and semi-glossy. The gloss range means the initial measurement based on 60° geometry as listed in Table 1. The reading is used to determine which type of geometry to be used. For example, if the initial reading is 40 GU, the result will be 40 GU because

Gloss Meter, Table 1 Gloss types

Gloss type	Gloss range	Measure with
Semigloss	10–70	60° geometry
High gloss	>70	20° geometry
Low gloss	<10	85° geometry

it is within the semigloss range, only using 60° geometry. If the initial reading is 78 GU, a new reading should be obtained using a 20° geometry gloss meter.

Gloss Meter Industry Standards

The following lists various national or international standards for measuring gloss [4]. Many industries adopt the 20°/60°/85° geometries as recommended in ISO 2813 and ASTM D523.

General Gloss Measurement

Standards	Description
ASTM D523 1999 (USA)	Test method for specular gloss. The principal ASTM specular gloss standard. Very similar to ISO 2813
ASTM D3928 1998 (USA)	Test method for evaluation of gloss or sheen uniformity
ASTM D4039 1999 (USA)	Test method for reflection haze of high-gloss surfaces
ASTM D4449 1999 (USA)	Test method for visual evaluation of gloss differences between surfaces of similar appearance

(continued)

Standards	Description
ASTM D5767 1999 (USA)	Test methods for instrumental measurement of distinctness of image gloss of coating surfaces
ASTM E340 1997 (USA)	Test methods for measurement of gloss of high-gloss surfaces by goniophotometry
MFT 30-064 (South Africa)	Local version of ASTM D523
JIS Z8741 1997 (Japan)	Method of measurement for specular glossiness

Paint

Standards	Description
ISO 2813 1994 (International)	Paints and varnishes – determination of specular gloss of nonmetallic paint films at 20°, 60°, and 85°. The principal ISO specular gloss standard. Very similar to ASTM D523
BS 3900:Part D5 1995 (UK)	Methods of test for paints – optical tests on paint films – measurement of specular gloss of nonmetallic paint films at 20°, 60°, and 85°
DIN 67530 1982 (Germany)	Reflectometer as a means for assessing the specular gloss of smooth painted and plastic surfaces
NFT 30-064 1999 (France)	Paints – measurement of specular gloss at 20°, 60°, and 85°
AS 1580 MTD 602.2 1996 (Australia)	Paints and related materials, methods of test – introduction and list of methods
JIS Z8741 1997 (Japan)	Specular glossiness – method of measurement
SS 18 41 84 1982 (Sweden)	Paints and varnishes – measurement of specular gloss of non-metallic paint films at 20°, 60°, and 85°

Plastics

Standards	Description
BS 2782: Pt 5, Method 520A 1992	Methods of testing plastics – optical and color properties, weathering – determination of specular gloss. Similar to ISO 2813

(continued)

Standards	Description
ASTM D2457 1990	Test method for specular gloss of plastic films and solid plastics specifies the primary standard as a perfect mirror with a defined gloss value of 1000. 20°, 60°, and 45°; the 45° method is as ASTM C346 for ceramics

Metals

Standards	Description
BS6161: Part 12 1987	Methods of testing for anodic oxidation coatings on aluminum and its alloys – measurement of specular reflectance and specular gloss at angles of 20°, 45°, 60°, or 85° Reference standard BS 3900: Part D5 (1980); technically equivalent to ISO 7668; replaces BS 1615:1972. At 45°, the dimensions of source image and receptor aperture are as for 60°. Squares with sides equal to the shorter sides of the rectangles are also recommended. Alternatively, total reflection in a 45° prism is used as a reference; source image and receptor aperture are then circular, both with angular diameter $3.44^\circ \pm 0.23^\circ$ (1.5 ± 0.1 mm at a focal length of 25.4 mm)
ISO 7668 1986	Anodized aluminum and aluminum alloys – measurement of specular reflectance and specular gloss at angles of 20°, 45°, 60°, or 85°
ISO 5190	Anodizing of aluminum and its alloys – evaluation of uniformity of appearance of architectural anodic finishes – determination of diffuse reflectance and specular gloss. ECCA T2 (European Coil Coating Association). Specular gloss at 60°

Paper

Standards	Description
DIN 54502 1992	Testing of paper and board; reflectometer as means of assessing the gloss of paper and board
ASTM D1223 1998	Test method for specular gloss of paper and paperboard at 75°. Has

(continued)

Standards	Description
	unusual converging beam geometry. Specifies the primary standard as black glass of refractive index 1.540, not 1.567, at the sodium D-line having a defined gloss value of 100
ASTM D1834 1995	Test method for 20° specular gloss of waxed paper. Another unusual converging beam geometry, different to the previous one
TAPPI T480 OM-90 1990 (USA)	Specular gloss of paper and paperboard at 75°. Same text as ASTM D 1223
TAPPI 653 1990	Specular gloss of waxed paper and paperboard at 20°. Same contents as ASTM D 1834
JIS Z8142 1993 (Japan)	Testing method for 75° specular gloss

Furniture

Standards	Description
BS 3962: Part 1 1980	Methods of testing the finishes of wooden furniture – assessment of low angle glare by measurement of specular gloss at 85°. Similar to ISO 2813: 1978

Floor Polish

Standards	Description
ASTM D1455 1987	Test method for 60° specular gloss of emulsion floor polish. Reference standard ASTM D 523

Ceramics

Standards	Description
ASTM C346 1987	Test method for 45° specular gloss of ceramic materials. Reference standard ASTM D 523
ASTM C584 1981	Test method for 60° specular gloss of glazed ceramic white wares and related products. Reference standard ASTM D 523 {Sheen}

Fabrics

Standards	Description
BS 3424: Method 31: Part 28 1993	Testing coated fabrics – determination of specular gloss

Goethe, Johann Wolfgang von

Rolf G. Kuehni
Charlotte, NC, USA

J. K. Stieler, 1828

Biography

Goethe was born on August 28, 1749, in Frankfurt, Germany, to a lawyer and the daughter of the mayor of Frankfurt. He studied law in Leipzig and Strasbourg (France). Based on his early fame as a poet and novelist, Goethe, at age 26, was invited by the 18-year-old Duke of Sachsen-Weimar to join his court as an advisor. He moved to Weimar where he remained until his death on March 22, 1832. At times he worked as a diplomat and a public servant for the duke. He became known as the preeminent German poet, novelist, and playwright. The philosophical nature of much of his writing and his battle with Kant influenced several later philosophers, such as Hegel, Schopenhauer, Nietzsche, and

Wittgenstein. Goethe's interests were very broad, including pictorial art and certain aspects of science, most importantly in the latter the metamorphosis of plants, where he displayed a pre-Darwinian point of view, as well as the source and nature of color experience. He considered his *Farbenlehre* (Theory of Colours) [1] the most important of his works.

Goethe's views on science were strongly influenced by the seemingly very complex relationship between objectivity and subjectivity. He believed strongly in experimentation, with variability in conditions and multiple replications, which might lead to objective truths. Circa 1793, Goethe wrote an essay *Der Versuch als Vermittler von Objekt und Subjekt* (The Experiment as Mediator Between Subject and Object) which he shared with his friend, the poet Friedrich Schiller, in 1798 in which he described the value of scientific experiments as a bridge between subjectivity and objectivity and the possibility of establishing via multiple experiments of this kind the existence of objective laws of nature [2]. It was only published in print in 1823.

Major Accomplishments/Contributions

His interest in color began early in his life and received input during his extended journey to Italy in 1787 where he began studying Leonardo da Vinci's manuscripts on painting. His first writings on the subject of color date from 1791 *Beiträge zur Chromatik* [Contributions to Chromatics], 1792 *Von den Farbigen Schatten* (Concerning Colored Shadows), and 1794 *Versuch, die Elemente der Farbenlehre zu entdecken* (Attempt at Discovering the Elements of Color Theory). *Zur Farbenlehre*, in three volumes, was published in 1810, the same year P. O. Runge (well acquainted with Goethe) published his *Farben-Kugel* (Color Sphere). The first volume of *Farbenlehre* presents his description and interpretation of physiological colors, physical colors, and chemical colors; a chapter on the possibly singular natural source of color experience; a chapter about the relationship of color science to

other intellectual domains such as philosophy, mathematics, general physics, natural history, etc.; and one on the general esthetics of color. volume 2 is an extended attack on and critique of the color work of Isaac Newton, its main component being the “unnatural” methodology used by Newton when splitting daylight into its spectral components, replaced by Goethe’s method of investigating the effect of the prism when viewing contrasting boundaries in daylight. The result in the former case is the classical spectrum of colors and in the latter the series of so-called boundary or edge colors (for an informative discussion of boundary colors, see Ref. [3]). Recent complex optical experiments have shown that there is no discrepancy between Newton’s and Goethe’s findings (e.g., Ref. [4]). The third volume consists of an extended, if somewhat prejudiced, review of the history of color science (*Geschichte der Farbenlehre*), beginning with the ancient Greeks and ending with contemporaries of Goethe.

Goethe’s fundamental view of perceived colors was that they are the result of interaction between lightness and darkness, an idea already introduced by Aristotle. Goethe saw it confirmed by his experience with boundary colors when viewing edges of white and black fields through a prism, for example, viewing through it the hexagonal charts of Fig. 1, illuminated by daylight.

Goethe devised a color circle consisting of six hues in three complementary pairs, with a purplish red on top, followed on the left, warm side by orange and yellow, and on the cold right side by violet and blue, with green on the bottom. Colors diametrically opposite are approximately complementary. Such opposing colors were viewed by Goethe as harmonic pairs. He also used their relationships in the circle to demonstrate presumed psychological effects.

The response to Goethe’s *Farbenlehre* was mixed. However, in a commentary of 1892 Hermann von Helmholtz said: “And I for one do not know how anyone, regardless of what his views about colors are, can deny that the theory [Goethe’s] in itself is fully consequent, that its assumptions, once granted, explain the facts treated completely and indeed simply” [5].

Goethe, Johann Wolfgang von, Fig. 1 Partial collection of color-related equipment and materials owned by Goethe in the Goethe-Nationalmuseum in Weimar

The English painter Charles Eastlake published in 1840 a translation of Part I as “Theory of Colours” [6]. It became an important source of information for painters, such as J. M. W. Turner. In an introduction to a modern version of the translation in 1970 (remaining in print today), D. B. Judd wrote: “This book can lead the reader through a demonstration course not only in subjectively produced colors (after images, light and dark adaptation, irradiation, colored shadows, and pressure phosphenes), but also in physical phenomena detectable qualitatively by observation of color (absorption, scattering, refraction, diffraction, polarization, and interference)” [7].

Goniometer

Definition

A goniophotometer is an instrument for measuring light distribution in terms of the luminous intensity or illuminance distribution of a light source, a luminaire, a self-luminous display, or a surface by changing the position of a photometer or a goniometer at a clearly defined geometry.

A typical goniophotometer usually consists of a mechanical device or robotic jib to support the luminaire to be measured and a photometer or a spectroradiometer, and allows their relative position to be changed to form a spherical locus [1].

By analyzing the optical data of the definite angle of spectral irradiance, the total luminous flux, spectral radiant flux, and color quantities can be obtained. Spectral radiant flux refers to the sum of all the radiant energy emitted per unit of time, by a light source over a specific range of a spectrum. Spectral radiant flux is the basis for deriving important luminaire parameters such as total luminous flux, radiant flux, luminous efficacy, chromaticity, correlated color temperature, color rendering index, etc.

Overview

A typical goniophotometer includes a luminaire and a photometer. There are three common types of goniophotometer, according to the different geometrical arrangements of the two components. The first type of goniophotometer rotates the luminaire along the two assigned perpendicular axes with the photometer fixed. The second type of goniophotometer rotates the photometer instead of the luminaire. The third type of goniophotometer rotates the luminaire along one axis, and its photometer moves along the other axis. The relative orientation of the luminaire and the photometer is then adjusted [2–4].

However, it is complicated to design a goniophotometer, compared with an integrating sphere to measure the luminous flux of the luminaire, because goniophotometric measurements require a large, dark room, a long period for measurement, and great precision of movements. Moreover, for some designs, the luminaire must be rotated, which can cause errors because of its sensitivity to the burning position and draft of the radiant flux. Some luminaire-mounting mechanisms of the goniophotometer can also generate shadow, which affects the luminous flux measured [5, 6] (Fig. 1).

Goniophotometer,

Fig. 1 The International Commission on Illumination type C, spectral-based goniophotometer

The spectral radiant flux measurement goniophotometer uses a spectroradiometer to measure the spectral power distribution of the luminaire at a specific angle. In practice, the spectroradiometer should be calibrated, and the stray light during measurement should be eliminated to achieve measurement accuracy. Stray light is one of the most common sources of measurement inaccuracies for the spectroradiometer. Traditionally, a tunable laser was used to correct the stray light [7]. A novel spectral stray light correction technique for spectroradiometer was then developed. It removes, primarily through an optical frequency comb technique, all stray light that does not fall within a certain fixed wavelength range. This prevents stray light, from indeterminate light sources within the spectroradiometer, from interfering with the measurement process, thus enhancing the accuracy of the measurement [8].

Figure 2 shows a spectral-based goniophotometer, including a detector head module and photodiode array type spectroradiometer set in the jib of the goniophotometer. The luminaire is located in the center of the goniophotometer. The detector head module is arranged according to different predetermined geometries. The key to achieving great

measurement accuracy is to avoid rapid movement, which can cause air flow and vibration.

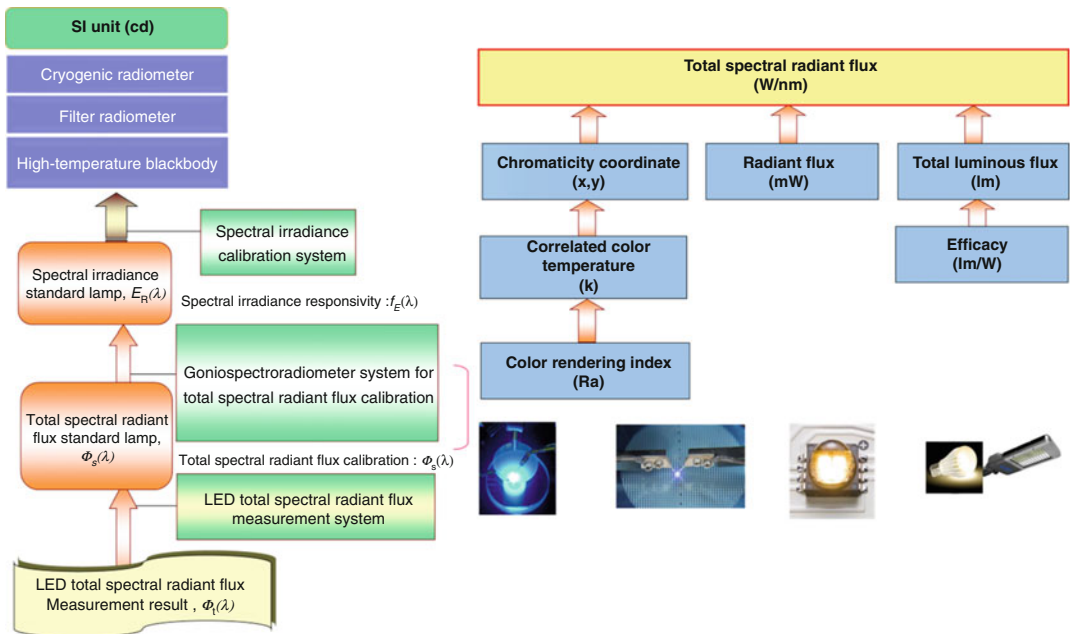

The spectral radiant flux, by integrating the spectral irradiance in the definite angle, may be calculated using the equation below:

$$\Phi(\lambda) = r^2 \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi} E(\theta, \phi, \lambda) \sin \theta d\theta d\phi \quad (1)$$

where $\Phi(\lambda)$ is the spectral radiant flux in W/nm unit; $E(\lambda)$ is the spectral irradiance in W/m² nm unit, and r is the radius between the reference plane of the detector and the luminaire.

Light-emitting diode (LED) lighting parameters consist of lighting comfort, product safety, lifespan, and characteristics. Spectral radiant flux is the basis for radiometry and chromaticity parameters and specifications, from which total luminous flux, radiant flux, luminous efficacy, chromaticity, correlated color temperature, color rendering index, etc., can be derived, as shown in Fig. 3. LED total spectral radiant flux is measured using an LED total spectral radiant flux measurement system. The total spectral radiant flux standard lamp carries the total spectral radiant flux and transfers the standard from the goniophotometry measurement system. By using a spectral irradiance standard lamp, the spectral radiant flux

Goniophotometer, Fig. 2 Schematic diagram of a spectral-based goniophotometer

Goniophotometer, Fig. 3 The metrological traceability chain of the total spectral radiant flux standard lamp calibration system

standard is transferred to the irradiance standard and traced to SI units. Therefore, the spectral radiant flux measurement standard can be traced to the SI unit, the candela (cd).

Compared with the sphere-based instruments, a spectral-based goniophotometer (goniospectroradiometer) provides absolute measurement with greater accuracy, than a calibrated flux standard

lamp with a known total spectral radiance. Goniophotometers also report the spatial light distribution data and measure the luminous flux of the particular light distribution of a luminaire, such as a parabolic aluminized reflector lamp (PAR lamp) or a curved lamp. Also, a photodiode array type spectroradiometer should have spectral response calibration, stray light correction,

sensitivity, and linearity certification to ensure accurate measurement.

John Guild was a British scientist who worked at the National Physical Laboratory (NPL) at Teddington in England. Guild spent the majority of his professional life making outstanding contributions to the development of a wide variety of optical instruments and techniques [1].

In the 1920s he wrote several papers, published in the Transactions of the Optical Society, describing the fundamentals of colorimetry which have formed the basis of the discipline ever since.

He measured, for seven observers, the way in which the colors of the spectrum are matched by beams of red, green, and blue light added together. This work, together with a similar study carried out by David W. Wright, with ten additional observers, formed the basis of the international standard for measuring color, the CIE 1931 Standard Colorimetric Observer. The quality of this experimental work was so high that this standard, although now more than 80 years old, is still in universal use. Guild was largely responsible for making this work the basis of the international

system of colorimetry that is still in use today. In collaboration with T. Smith, also of the NPL, he devised the transformation of the experimental results into the XYZ system that is the form in which the standard is used.

In spite of having played a key role in establishing the basis and original standard of colorimetry, after 1931 Guild transferred his interests to other spheres of work and took little further part in the subject. However, he retained his interest in colorimetry and was instrumental in the formation of the Colour Group in the United Kingdom where he was the second chairman of the group (1943–1945) and one of the first honorary members in 1966 [1].

Some of his more important and relevant publications pertaining to this field are listed:

- J. Guild: An equipment for visual spectrophotometry. *Trans. Opt. Soc.* **26**, 74–94 (1924–1925)
- J. Guild: The transformation of trichromatic mixture data: algebraic methods. *Trans. Opt. Soc.* **26**, 95–108 (1924–1925)
- J. Guild: The geometrical solution of colour mixture problems. *Trans. Opt. Soc.* **26**, 139–174 (1924)
- J. Guild: A trichromatic colorimeter suitable for standardisation work. *Trans. Opt. Soc.* **27**, 106–129 (1925–1926)
- J. Guild: A criticism of the monochromatic-plus-white method of colorimetry. *Trans. Opt. Soc.* **27**, 130–138 (1925)
- J. Guild: On a new method of colorimetry. *Trans. Opt. Soc.* **27**, 139–160 (1925–1926)
- T. Smith, J. Guild: The CIE colorimetric standards and their use. *Trans. Opt. Soc.* **33**, 73–134 (1931–1932)
- J. Guild: The colorimetric properties of the spectrum. *Phil. Trans. Roy. Soc. (London) A* **230**, 149–187 (1931)

Synonyms

[Iodine lamps](#); [Quartz halogen lamps](#)

Definition

Lamps that produce light as a result of electrical current through a metal wire, contained in a small transparent bulb that heats the metal to incandescence. The bulb also contains halogen that reacts with the vaporized metal, so that bulb blackening by vaporized metal is minimized.

Halogen Lamps

During the operation of an incandescent lamp, tungsten evaporates from the filament and settles on the coldest place inside the lamp (the bulb wall), causing lamp blackening, which leads to a considerable depreciation of the light output during lamp life. In order to keep lamp blackening, and the corresponding light loss, within acceptable limits, bulbs of regular incandescent lamps are relatively large. But in order to be able to operate small-bulb high-light-output incandescent lamps, special measures have to be taken to prevent bulb blackening, which in these small bulbs would quickly lead to unacceptable light losses. The solution to this problem is to introduce halogen into the bulbs. These lamps are called halogen incandescent or, in short, halogen lamps [1, 2]. Thanks to their compactness they are extremely suitable for use in small reflectors to create well-defined light beams. They are widely used for accent lighting and in car headlamps.

However, because of the relatively low efficacy and short lifetime of halogen lamps, the more efficient and longer-life gas discharge and solid-state lamp alternatives have become increasingly more important in all these segments.

Halogen Cycle Principle

One way to eliminate bulb blackening is to add a small quantity of halogen (bromide or iodine) to the fill gas. Under the influence of the hot filament, evaporated tungsten particles chemically combine with the halogen particles. If the temperature is sufficiently high (bulb temperature at least 250°C), the resulting mixture will remain floating in a gaseous state, preventing it from condensing on the coldest part of the lamp bulb to create bulb blackening. The extremely high temperature in the vicinity of the filament causes a chemical reaction that splits the mixture into its original components, tungsten and halogen particles, and the former return to the filament. This phenomenon is called the halogen cycle. It is illustrated in Fig. 1.

A tungsten particle that escapes from one spot of the filament does not return to precisely the same spot. As a result, the lamp will eventually burn out, because there will always be some part of the filament that will become weak over the

course of time, but clearly later than in a regular incandescent lamp. This means that the filament can be heated up to a higher temperature (up to 3000 K instead of 2750 K as in the case of a regular incandescent lamp) while having a longer life. Halogen lamps offer two to five times the life of regular incandescent lamps, rising from 1000 to 2000–5000 h. The higher filament temperature also increases both the luminous efficacy by 10–50% relative to regular incandescent lamps and the color temperature up to 3000 K.

Materials and Construction

Bulb

Since a halogen bulb is so small, it becomes so hot that ordinary glass, as used with incandescent lamps, cannot be used because it would melt. Halogen bulbs are therefore made out of quartz, which can withstand high temperatures and mechanical stress. In the manufacturing process, it can be handled similarly to glass (Fig. 2).

Filament

The single- or double-coiled tungsten filament can be placed axially or transversely in the halogen capsule. The placement has consequences for

Halogen Lamp,

Fig. 1 The halogen cycle
[3]

Halogen Lamp, Fig. 2 Halogen lamp with its components. The bulb can be as small as approximately 10×15 mm

both the efficacy and the light distribution of the lamp.

Fill Gas

As in regular incandescent lamps, a gas filling of krypton or xenon is used to reduce filament evaporation.

Lamp Cap

Halogen lamps are available with a large variety of lamp caps and corresponding bases: two-pin caps and twist caps that ensure that the optical center of the lamp is always in the correct position, ceramic lamp caps for high-voltage, high-lumen-output lamps that become very hot, and “normal” Edison and bayonet caps for high-voltage halogen lamps that can be used just as regular incandescent lamps.

Properties

Energy Balance

Thanks to the higher working temperature of the halogen incandescent lamp, it is more efficient than a regular incandescent lamp. Some 12% of the input power of a halogen lamp is radiated as visible light. Compare this with the 8% of a regular incandescent lamp. The remaining power is lost as heat (through conduction, convection, and infrared radiation).

Luminous Efficacy

At 15–25 lm/W, the luminous efficacy of a halogen lamp is a factor 2–2.5 higher than that of an incandescent lamp. With the infrared-reflecting coating technology (see next section “[Product Range](#)”), the efficacy increases to some 35 lm/W. As with regular incandescent lamps, the lower the wattage, the lower the efficacy. There are halogen lamps where priority has been given to a long life at the expense of a somewhat lower efficacy (e.g., 5000 h and 15 lm/W), and conversely, there are those where the emphasis is on efficacy and not so much on lifetime (e.g., 2000 h and 25 lm/W).

Although the efficacy of halogen lamps is clearly higher than that of regular incandescent lamps, it is relatively low compared with that of gas discharge and solid-state light lamps.

Lumen-Package Range

Common types of halogen lamps are available in the range from some 50 to 2000 lm (corresponding wattage range approximately 5–100 W). Double-ended mains-voltage halogen lamps are available in versions up to some 25,000 lm (1000 W version).

Color Characteristics

Halogen lamps have a continuous spectrum radiating more energy at long wavelengths than at short wavelengths (Fig. 3). Because of the somewhat higher temperature of the filament in halogen lamps compared to that of the filament in regular incandescent lamps, the spectral energy distribution shifts slightly toward shorter wavelengths. Depending on the version (lower

Halogen Lamp,**Fig. 3** Relative spectral energy distribution of a halogen lamp [3]

efficacy/longer life or higher efficacy/shorter life), halogen lamps have a color temperature of between 2800 and 3000 K, respectively. Their color temperature is always slightly higher than that of regular incandescent lamps, thus giving them a somewhat cooler white light. The color rendering index is 100.

Lamp Life

Regular halogen lamps have a lifetime that is at least twice as long as that of regular incandescent lamps, thus at least 2000 h. As explained above, with some halogen lamps, priority is given to efficacy at the expense of lifetime, viz., the 2000 h versions. Versions, where the priority is given to lifetime, can have a life of up to 5000 h.

Lamp-Lumen Depreciation

Thanks to the halogen regenerative cycle, lamp blackening is minimal. Consequently, lumen depreciation with halogen lamps is very small.

Burning Position

With certain exceptions, halogen lamps have a universal burning position. The exceptions are the high-voltage, high-wattage (750 W or more) double-ended types. Here the coiled tungsten filament is so long that with a position that is not near horizontal, the coil would sag so much that the individual coil windings would touch each other, leading to a short circuit.

Run-Up and Reignition

Like regular incandescent lamps, halogen lamps give their full light output immediately after switch on and after reignition.

Switching

The switching behavior of halogen lamps is the same as that of regular incandescent lamps.

Dimming

Halogen lamps can be dimmed in the same way as regular incandescent lamps. Just as with regular incandescent lamps, the phase-cutting system is the more efficient system and is usually employed. Below a certain dimming point, the lamps cool down so much that the halogen cycle will no longer function. From this point on, the filament starts evaporating, just as with a normal, dimmed incandescent lamp. The smaller bulb size of the halogen lamp leads to more blackening in this situation than is the case with regular incandescent lamps. However, since the filament in the dimmed situation is cooler than in the undimmed situation, dimming does not have a real negative effect on lamp life.

Mains-Voltage Variations

The behavior of halogen lamps as a result of overvoltage is the same as with regular incandescent lamps. Only a few percent of overvoltage results in a drastically reduced lamp life. For example, a permanent overvoltage of 5% reduces lamp life by 50%.

UV Component

Regular incandescent lamps radiate little UV. This is because the spectrum quickly falls off at the short-wavelength part of the spectrum. What little UV that remains is reduced to near zero because regular glass (the bulb material of incandescent lamps) is an excellent absorber of UV radiation. Halogen lamps radiate more UV because of the

Halogen Lamp,

H

higher operating temperature of the filament and because of the fact that regular quartz bulbs, unlike glass bulbs, do not absorb UV radiation. In order to limit harmful or damaging UV radiation from halogen lamps, the quartz used today for most halogen lamps is doped with UV-absorbing material (UV-blocking quartz).

Product Range

Grouping of Halogen Lamps

As far as the operating voltage is concerned, halogen lamps can be placed into two groups (Fig. 4).

- Lamps operating on low voltage (6, 12, and 24 V, where the 12 V versions are most common)
- Lamps operating on mains voltage

Low-voltage halogen lamps are usually single-ended. Mains-voltage versions can be either single-ended or double-ended, according to whether the electrical connection is at one end of the lamp (Fig. 5) or on two separated ends of the lamp (double), as illustrated in Fig. 6.

Single-ended halogen lamps are available both as “naked” bulbs (capsules such as in Fig. 7) and as reflector lamps. The reflector versions exist in three different types: mirror-coated glass reflectors, aluminum reflectors, and pressed-glass PAR reflectors (Fig. 5). The mirror-coated glass reflectors are produced with plain mirror-coating versions and with a dichroic coating (so-called cool-beam type; see later in this chapter).

Some mains-voltage halogen bulbs (both single-ended and double-ended) are housed in an extra outer glass bulb or glass tube with the

Halogen Lamp, Fig. 6 Double-ended mains-voltage halogen lamp

Halogen Lamp, Fig. 7 Low-voltage halogen capsules

familiar Edison or bayonet lamp cap. These are called double-envelope halogen lamps (Fig. 8). They are the more-energy-efficient replacements for regular incandescent lamps.

Cool-Beam Halogen Lamps

A special version of halogen lamps, the so-called cool-beam lamps, makes use of the interference principle. They consist of a small halogen bulb (capsule) housed in a reflector with an interference metal coating, also known as a $\frac{1}{4} \lambda$, or dichroic coating (Fig. 9). This coating splits the radiation coming out of the halogen capsule into an infrared part (heat), which is transmitted through the coating and not reflected by it, and a visible part that is reflected but not transmitted. The practical result is that the mirror coating reflects practically all of the light while allowing the infrared to pass through it to the back of the reflector, taking

Halogen Lamp,

Fig. 9 Dichroic interference coating (shown in yellow) in a cool-beam halogen lamp [3]

**Halogen Lamp,**

Fig. 10 Infrared-reflective coating based on the interference principle used to reflect the infrared radiation of the filament back to the filament while allowing visible light to pass through [3]

about two-thirds of the heat from the light beam. Thus, only one-third of the generated heat is contained in the light beam. This is why these lamps are referred to as “cool-beam” or “dichroic” halogen lamps. When using this type of lamp in an installation, it is essential to ensure that the heat radiated from the rear of the lamp can be dissipated backwards. The thickness of the coating layer is slightly different for radiation arriving at the coating from different directions. This also means that the wavelength of the radiation where it is split into reflected and transmitted components is slightly different for different directions.

Halogen Lamps with Infrared-Reflective Coating

Another special version of the halogen lamp also makes use of the interference coating principle but

for a completely different reason. Here the reason is thermal recovery: the interference coating applied to the halogen bulb is now so dimensioned that it reflects the infrared radiated from the filament back to the filament while allowing visible light to pass through (Fig. 10). In this way less external energy is needed to keep the filament at the required temperature, thus improving the efficacy of the lamp (by up to 25–35 lm/W). Moreover, the heat contained in the light beam is reduced by approximately 40%.

Biography

Helmholtz was born on August 31, 1821 in Potsdam near Berlin, Germany, into a well-educated family. His father, an educator, taught him the classical languages and introduced him to philosophy. Helmholtz studied medicine in Berlin under physiologist Johannes Müller, at the same time attending lectures in physics and mathematics. Müller was an adherent of the then broadly accepted philosophical nativism. Helmholtz spent much of his life finding objective arguments against nativism and in favor of empiricism. After spending several years in military service in Potsdam and a stint as associate professor of physiology at the Prussian University, he became a full professor of anatomy and physiology in Bonn. Three years later, he moved to the University of Heidelberg and in 1871 became professor of physics at the University of Berlin, where he remained until his retirement. Helmholtz had a broad range of interests, from astronomy to physics, physiology, and the relationship between the physical world and human sensory perception. In 1847 he wrote an important article on the conservation of physical force [1]. In 1850 Helmholtz invented the ophthalmoscope for inspecting the interior of eyes for medical purposes and revolutionized the practice of ophthalmology [2]. Among Helmholtz's many students were H. R. Hertz, M. Planck, A. A. Michelson, W. Wundt, and W. Kohlrausch (the codiscoverer of the Helmholtz-Kohlrausch effect).

Major Accomplishments/Contributions

In sensory perception, he specifically covered hearing and, most extensively, vision. His most important publication is *Handbuch der physiologischen Optik* (Treatise on Physiological Optics), a 900+-page work whose first edition was published in 1867 when he was in Heidelberg [3]. Its main sections are (1) anatomical description of the eye; (2) physiological optics; (3) dioptrics of the eye; (4) sensations of vision, including simple colors and compound colors; (5) intensity and

**Helmholtz, Hermann
Ludwig von,**

H

duration of the sensation of light; (6) contrast (including colored shadows); and (7) duplicity theory. A second edition authored by Helmholtz was published posthumously in 1896, supervised by Helmholtz' assistant Arthur König who also added over 7800 literature references [4]. A third edition was published in 1909, consisting of the second edition, with contributions by A. Gullstrand, J. von Kries, and W. Nagel. It was translated into English by J. P. C Southhall and published with an additional contribution by the Optical Society of America [5].

Helmholtz built his trichromatic theory of color vision on Newton's findings, Young's theory of three sensor types in the eye, Maxwell's experimental findings of color mixture, and his own extensive experimental data concerning various aspects of color vision. He developed a spectral light mixture apparatus (see portrait) with which, after initial unsatisfactory results causing the mathematician H. Grassmann to challenge his data, he established the first detailed quantitative data for the relationship between color stimuli and percepts. Mathematical models of his findings and concepts were a standard procedure in his work. Under his guidance, his assistants König and Dieterici developed in 1885 a first quantitative version of a trichromatic chromaticity diagram (Fig. 1) [4].

While Helmholtz developed an experimentally supported general psychophysical theory of vision, he was also concerned about and experimented with many additional phenomena of the human visual system. He is the first to mention color constancy, saying that "we always start out forming a judgment about the colors of bodies, eliminating the difference of illumination by which the body is revealed to us" [6]. The color vision theory of Helmholtz, based on Young's conjecture of three sensor types, is known as the Young-Helmholtz theory of trichromatic color vision.

His rival Ewald Hering developed a theory of color vision essentially based on psychology to which he gave a presumed physiological basis. Both views attracted followers [7]. Today, the controversy has been narrowed but still remains. Interestingly, their expressed epistemological views are not as might be expected: Helmholtz viewed lights and colors as symbols. In 1852 he said: "Light and color percepts are only symbols for the relations of reality; with the latter they have as little and as much similarity or relationship as the name of a person or its written form with the person itself" [8]. Hering, on the other hand, believed that, in perception, our access to real objects is a direct one.

Helmholtz–Kohlrausch Effect

Hirohisa Yaguchi
Professor Emeritus, Chiba University, Chiba,
Japan

Synonyms

Additivity failure for brightness; Brightness-Luminance ratio: B/L

Definition

When a test stimulus of complex radiant power distribution is matched in brightness against a fixed “white” reference stimulus, it is generally found that the luminance of the chromatic test

stimulus is lower than the luminance of the reference stimulus. In other words, a chromatic stimulus of the same luminance as the “white” reference stimulus will, in general, appear brighter than the reference stimulus [1].

This phenomenon is caused by the failure of the additivity law of brightness. Helmholtz first noticed that the additivity law of brightness did not hold, and Kohlrausch studied this in detail, resulting in it being called the Helmholtz-Kohlrausch effect [2].

Overview

Even with chromatic stimuli of the same luminance, colorful stimuli appear brighter than white stimuli. This Helmholtz-Kohlrausch effect is caused by the difference in luminance and brightness. The spectral luminous efficiency function used to define luminance is primarily based on measurements such as flicker photometry, which do not involve chromatic components. On the other hand, brightness is determined by a direct comparison method in which chromatic components affect the brightness criterion, that is, the brightness sensation includes chromatic components in addition to the luminance component. Therefore, even color stimuli with the same luminance vary in brightness appearance, depending on the amount of chromaticness. In addition, the contribution of the chromatic component to the brightness causes an additivity failure in brightness.

Definition of Luminance

The luminance at a point on a surface and in a given direction is the quotient of the luminous intensity in the given direction of an infinitesimal element of the surface containing the point under consideration, by the orthogonally projected area of the surface element on a plane perpendicular to the given direction. According to this geometric definition, luminance is a photometric unit that expresses the perceived brightness of an object.

As a photometric unit, luminance is defined by the following equation with the standard spectral

luminous efficiency function defined by the CIE in 1924:

$$L = K_m \int L_{e,\lambda} V(\lambda) d\lambda, \quad (1)$$

where L means luminance, K_m is the maximum luminous efficacy, $L_{e,\lambda}$ is the spectral radiance, and $V(\lambda)$ is the luminous efficiency function.

Definition of Brightness

Brightness is the attribute of a visual impression according to which a given visual stimulus is presented appears to emit more or less light.

Problems in Photometry

Luminance, which is a unit of photometry, may not always correspond to brightness, which is a visual impression. This problem may be due to two factors in the definition of luminance. First, the luminous efficiency function $V(\lambda)$ itself may be an error. It had been long realized that the weight of the short wavelength region was too low. In 1951, Judd published his modification [3] of the CIE luminous efficiency function now called CIE 1988 $V_M(\lambda)$ [4]. A much more troublesome problem arises from the fact that luminous efficiency functions depend on the visual assessment.

Second, the additivity assumption may have failed. The integral in equation (1), the definition formula of the luminance, implies that the luminance of a stimulus composed by mixing stimuli of different wavelengths can be expressed by adding the luminance of the constituent monochromatic stimuli. In other words, it is assumed that the additivity law of luminance must be maintained. The additivity law is also referred to as Abney's law.

Luminous Efficiency Functions

A luminous efficiency function gives the ratio of the radiant power of a monochromatic stimulus of

wavelength λ_m to that of wavelength λ , when the two monochromatic stimuli produce luminous sensations that under given observing conditions and in accordance with some specified criterion are judged to be equivalent or the same, λ_m being chosen so that the maximum value of this ratio is unity.

The luminous efficiency function differs depending on the criteria embodied in the visual judgment. The major measurement procedures and criteria used in determining luminous efficiency functions include flicker photometry, direct heterochromatic brightness matching, step-by-step brightness matching, minimally distinct border, color matching, absolute threshold, increment threshold, visual acuity, and critical flicker frequency. The luminous efficiency functions by these methods are classified into two types. First, the flicker photometry is a typical example, and color does not contribute to the visual criteria. The 1924 CIE $V(\lambda)$ used in the definition of luminance was derived primarily from flicker photometry [5]. In the flicker photometry, the observer is asked to adjust the quantity of a chromatic light which temporally alternates with a reference light, until minimum flicker is obtained. The same type of flicker photometry was also obtained by the minimally distinct border, color matching, and critical flicker frequency methods. Even in heterochromatic brightness matching, when the visual field size is very small such as a point source is used, the luminous efficiency functions are close to the flicker photometry type.

On the other hand, the second type, which is typically the direct heterochromatic brightness matching, is affected by the difference in color on the judgment criteria. Since brightness matching is static, the criterion of brightness seems to be evaluated by not only the luminance component but also the chromatic component. There are many studies showing that the luminous efficiency function obtained by heterochromatic brightness matching has a broader curve than the CIE $V(\lambda)$ [6–8]. Based on early experimental data from these studies, the CIE provides a mean luminous efficiency function for heterochromatic brightness matching for 2° and 10° visual field [9]. Figure 1 shows the luminous efficiency

Helmholtz–Kohlrausch Effect, Fig. 1 Comparison of various luminous efficiency functions

function for heterochromatic brightness matching for 2° field, $V_{b,2}(\lambda)$ by comparing CIE1924 $V(\lambda)$, Judd's modification, CIE1988 $V_M(\lambda)$, and CIE2015 $V_F(\lambda)$ derived from the color matching functions [10]. $V_{b,2}(\lambda)$ shows higher efficiency than the other three luminous efficiency functions in the more saturated portion of the spectrum. It means that even if the luminance of each monochromatic light is set to be equal, the higher the saturation, the monochromatic light looks the brighter. The contribution of chromatic component to brightness is also based on another fact that the difference between the luminous efficiency function obtained by heterochromatic brightness matching and that obtained by flicker photometry is quite similar to the saturation-discrimination function obtained by measurements of just-noticeable colorimetric purity [8]. Since the saturation discrimination function is assumed to reflect the ratio of the quantity of activities of the chromatic channels to that of the

luminance channel, the difference between the two curves is considered to be related to the contribution of the chromatic components to brightness. The second type of luminous efficiency functions are also observed in the methods of the step-by-step brightness-matching, absolute threshold, and increment threshold methods.

Additivity Failures for Brightness

Luminance is defined on the assumption linear additivity of the contributions of different wavelengths as expressed by equation (1). Therefore, the visual criteria used for $V(\lambda)$ must obey the additivity law. The additivity law holds for minimum flicker which is the criterion in the flicker photometry used the basis for formulating the CIE 1924 $V(\lambda)$. The additivity law also holds for the criterion of minimally distinct border and for the criterion of visual acuity. Even in heterochromatic

Helmholtz–Kohlrausch Effect, Fig. 2 A schematic view of the additivity test for heterochromatic brightness matching

brightness matching, when a grating target or a fine checkerboard pattern is used, the additivity holds.

On the other hand, the additivity law is not obeyed with heterochromatic matching [7, 11]. Figure 2 shows a schematic view of a conventional additivity test of heterochromatic brightness matching. The radiances of monochromatic lights λ_1 and λ_2 be $L_{e,01}$ and $L_{e,02}$ that are matched to a white reference light in brightness, respectively, when they are presented separately. Next, monochromatic lights of these two wavelengths are mixed to match the brightness of the reference white light. The radiances of λ_1 and λ_2 be $L_{e,m1}$ and $L_{e,m2}$ are matched to the same white reference. The radiance ratios ρ_1 and ρ_2 are defined as follows:

$$\rho_1 = L_{e,m1}/L_{e,01} \quad (2)$$

$$\rho_2 = L_{e,m2}/L_{e,02} \quad (3)$$

The additivity can be evaluated by the value, $\rho_1 + \rho_2$, such that if $\rho_1 + \rho_2 = 1$ the additivity holds, if $\rho_1 + \rho_2 > 1$ it fails as a reduction type or subadditivity, and if $\rho_1 + \rho_2 < 1$ it fails also but as an enhancement type or superadditivity.

Helmholtz–Kohlrausch Effect, Fig. 3 $\rho_1 - \rho_2$ plots for 500–660 nm pair from three subjects. Arrows indicate ratios of ρ_1 to ρ_2 of perceived red-green equilibrium for each subject

A typical plot of ρ_1 vs ρ_1 is shown in Fig. 3 where $\lambda_1 = 500$ nm and $\lambda_2 = 660$ nm for three subjects [11]. All points are located in the upper right region of a dashed straight line of linear additivity to indicate a reduction type additivity failure between the red and green lights, although its amount varies among subjects. The asymmetrical nature of the additivity failure is clearly seen in all subjects in that the largest deviation from the dashed line occurs not at the ratio $\rho_1/\rho_2 = 1$ but at a ratio larger than unity. The two colors employed here, named red and green, are complementary with each other and there must exist a ratio of ρ_1 to ρ_2 to give a red-green equilibrium, that is, neither reddish nor greenish. In the experiment, the subjects were asked to indicate the perceived hue of the mixture at various ratios. The arrows in Fig. 3 show the ratio at equilibrium. It is noticed in Fig. 3 that the maximum brightness reduction point exhibited by the largest deviation from the dashed line coincides with the arrow position of each subject. That is, the brightness reduction becomes strongest at the red-green equilibrium. Similar results were obtained with a mixture of yellow and blue lights. The results show a strong evidence that the chromatic components contribute to the brightness.

Helmholtz–Kohlrausch Effect, Fig. 4 A physiological color vision model for luminance and brightness

Physiological Mechanism and Model for Brightness

Figure 4 shows a physiological model of luminance and brightness based on the most reliable color vision model. It has been recognized that luminous quantity as measured by flicker photometry relies only on the sum of the activity of the long-wave sensitive (L-) and middle-wave sensitive (M-) cones. The signal of the difference between the L- and M-cones, L-M goes to the red-green opponent color channel and the L cone. The signal of the difference between the sum of L- and M-cones (L + M) and S-cones is transmitted to the yellow-blue opponent color channel. Luminous sensation in the flicker photometry that determines luminance is performed in the luminance channel without the contribution of the opponent color channel, and the brightness assessment in the heterochromatic brightness matching is made of two opponent color channels in addition to the luminance channel. As shown in Fig. 5, when a red light and a green light are mixed, the color components are canceled out in the red-green opponent color channel, causing the additivity failures of brightness. In this case, a unit brightness of red plus a unit brightness of green makes a unit brightness of yellow, that is, $1 + 1 = 1$. As a result, even with chromatic stimulus of the same luminance, more

colorful stimulus looks brighter than desaturated stimulus, that is, the Helmholtz-Kohlrausch effect.

Several mathematical models have been proposed that explain the mechanism of brightness. Among them, Guth et al. [7] proposed the vector model shown in equation (4).

$$L^{**} = (A^2 + T^2 + D^2)^{1/2}, \quad (4)$$

where the brightness L^{**} called vector luminance is represented by the vector sum of a non-opponent mechanism A , a red vs. green system T , and a yellow vs. blue system D . Ingling et al. [12] proposed similarly orthogonal combination of the three visual channels show in equation (5)

$$S^2 = Q^2 \left[(r - g)^2 + (y - b)^2 + V_\lambda^2 \right], \quad (5)$$

where S is the visual response such as brightness, Q is light intensity, $(r - g)$, $(y - b)$, and V_λ is the sensitivity of red-green opponent system, yellow-blue opponent system, and the luminance system, respectively. Yaguchi et al. [11] proposed a non-linear vector model by modifying the Guth's model to explain the asymmetrical additivity failure shown in Fig. 3. In their model, the luminous efficiency function for brightness $V_b(\lambda)$ is provided as equations (6):

$$\begin{aligned} (\bar{a}_\lambda L_{e,\lambda})^2 + \left(|\bar{c}_{1\lambda} L_{e,\lambda}|^{0.64} \right)^2 + \left(|\bar{c}_{2\lambda} L_{e,\lambda}|^{0.36} \right)^2 &= 1, \\ V_b(\lambda) &= 1/L_{e,\lambda}, \end{aligned} \quad (6)$$

where $L_{e,\lambda}$ is the radiance of a monochromatic light to provide a unit brightness, $\bar{a}_\lambda$, $\bar{c}_{1\lambda}$ and $\bar{c}_{2\lambda}$ are spectral sensitivity functions of the achromatic channel, the red-green opponent color channel, and the yellow-blue opponent color channel, respectively, defined for the equal energy spectrum.

Brightness-Luminance Ratio, B/L

The luminous efficiency functions deal only with monochromatic light. When a test stimuli of

Helmholtz–Kohlrausch Effect, Fig. 5 Relation between the Helmholtz-Kohlrausch effect and the additivity failures of brightness

complex spectral radiant power distribution has been matched in brightness against a white reference stimulus, it is generally found that the luminance of the chromatic test stimulus is lower than the luminance of the reference stimulus. The degree of the Helmholtz-Kohlrausch effect is usually evaluated by the ratio of the luminance of a reference stimulus, B to the luminance of the test stimulus, L , when they are matched in brightness, so called the B/L ratio. Many experimental data on B/L of the complex stimuli have been reported [13]. Ware and Cowan summarized the data sets from more than 50 studies including spectral and nonspectral lights, and provided an equation in which B/L is expressed as a fifth polynomial function of the CIE (x , y) chromaticity coordinates [14]. Several models have been proposed to predict the B/L ratio of complex stimuli [7, 11, 15].

Hering, Karl Ewald Konstantin

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Karl Ewald Konstantin Hering was born on August 5, 1834, in Alt-Gersdorf, Saxony, son of a Lutheran pastor and his wife. He studied medicine at the University of Leipzig, obtaining an MD in 1860. For the next five years, he practiced medicine in Leipzig and pursued personal interests in vision on the side, publishing five *Beiträge zur Physiologie (Contributions to Physiology)* between 1861 and 1864 [1]. He was married in 1863, and he and his wife had a son, Heinrich Ewald, born in 1863. In 1865 he was appointed professor of physiology at the Josephinum Academy in Vienna. In 1870 he became the successor of J. E. Purkinje as professor of physiology at the University of Prague where he remained for 25 years, studying among other things the electrical actions of nerves and muscles, as well as the perception of light and color vision. In 1895 he was invited to join the University of Leipzig where he remained until his retirement in 1915. During his lifetime Hering assumed the role of anti-Helmholtz, scientifically and philosophically battling with him in regard to several subject matters [see, e.g., 2]. Hering died on January 26, 1918, in Leipzig.

Major Accomplishments/Contributions

Hering developed a theory, alternative in detail to that of Helmholtz, in regard to spatial perception based on images in two eyes. Publication of and the response to Helmholtz's first edition of the *Handbuch der Physiologischen Optik* in 1867 [3] provided a basis for Hering to consider in detail the issues of color perception and develop his own different theory. The result was the presentation in 1874 of six extended contributions to the Imperial Academy in Vienna, published in book format in 1878 as *Zur Lehre vom Lichtsinne (On the Theory of the Light Sense)* [4]. Hering considered the Young-Helmholtz theory to give too much weight to physics and not enough to the perceptual aspects of color. In response he developed an opponent-color theory postulating three

Hering, Karl Ewald Konstantin, Fig. 1 Superimposed images of the conceptual mixture of the four hue fundamentals in different ratios and the resulting hue circle

opponent pairs of fundamental colors (*Urfarben*), yellow-blue, red-green, and white-black, building on earlier ideas by H. Aubert and E. Mach. The hues are arranged according to simple principles in a hue circle (Fig. 1) (derived from two images in Ref. [4]. Image Tilo Hauke), the complete arrangement of all colors of a given hue being in a triangle, with white, black, and full color at the corners and “veiled” colors filling the interior. Hering called the result, in form of a double cone, the “natural color system.” He also proposed dissimilation/assimilation processes in the eye/brain as physiological basis of the opponent system, in opposition to the Young-Helmholtz theory involving three fundamentals. A commercial version of the Natural Color System atlas was introduced in 1979 by the Scandinavian Colour Institute [5].

Today, the perceptual aspects of Hering’s system continue to be considered essentially valid, with its physiological part having fallen short of reality. Despite many attempts, a psychophysical model of the four hues presumed fundamental and their mixtures that also meet other components of the colorimetric system is still lacking at this time, a major issue being the fact that while mean unique yellow and blue stimuli are essentially

complementary, unique green and unique red stimuli are far from it, complicating any model with the purpose of representing a perceptually meaningful and at the same time colorimetrically valid model.

Hertzsprung-Russell Diagram

Michael H. Brill

Datacolor, Lawrenceville, NJ, USA

Definition

A scatter graph of stars showing the relationship between each star’s absolute magnitude and its estimated surface temperature, or between optical and perceptual proxies for these quantities.

Absolute Magnitude and Temperature Scales

The absolute magnitude and temperature can be described as follows:

A star’s absolute magnitude is the attenuation (in factors $10^{-0.4}$) of the star Vega’s power (as received at 10 pc viewing distance [32.6 light-years]) to equal that of the star (also corrected to 10 pc). The convention that dimmer stars have higher magnitude is a historical

precedent that dates from Hipparchus (c. 190 BCE–c. 120 BCE), whose system of stellar magnitudes was based on visual assessment.

A star's surface temperature is estimated in one of three ways: by the observed color (an old way), by comparison of two sensor outputs such as blue and violet (a newer way), or by model prediction of the temperature of a black-body radiator with the same radiation power per unit star-surface area (the most modern way). The third way requires independent inference of the star's radius but assumes the star has an emissivity of 1. To acknowledge the lack of compensation for the true emissivity, the temperature on an H-R diagram is called "effective temperature."

Coordinate Conventions

Here are the coordinate conventions of the H-R diagram: Temperature increases from right to left, and magnitude (i.e., dimness) increases from bottom to top. Hence, dim red stars (red giants) appear near the upper right of the diagram, and bluish bright stars (such as white dwarfs) appear in the lower left. A long cluster of stars called the main sequence extends from the upper left to the lower right. Higher mass stars occur at the upper left of this sequence, and the Sun appears approximately in the middle. The main sequence is composed of stars that are currently dominated by hydrogen that is fusing into helium. According to currently accepted theory of stellar evolution, such stars will eventually migrate either to the red giants or white dwarf domain of the H-R diagram.

H-R diagrams are often depicted in color, either pseudocolor with a thermal code to show the temperature or coded according to star categories such as cluster membership.

History

The H-R diagram was originated by Danish astronomer Ejnar Hertzsprung and American astronomer Henry Norris Russell (https://en.wikipedia.org/wiki/Hertzsprung%E2%80%93Russell_diagram). Originally the diagram was based on visual

estimation of magnitude and color, and it was a research tool to help characterize stellar evolution before the mechanism of nuclear fusion was understood. After about the 1930s, the H-R diagram became based on objective measurements but was used less as a research tool and more as a way to illustrate the theoretically predicted evolution of stars through trajectories in the diagram.

High- and Low-Pressure Sodium Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Sodium gas discharge lamps](#)

Definition

A lamp that produces light as a result of an electrical discharge, generated between two electrodes, in a sodium vapor that is contained in a transparent bulb.

Sodium Gas Discharge Lamps

Sodium gas discharge lamps can be distinguished in two main groups: low-pressure sodium lamps

Modified and reproduced from [1] by permission of Philips Lighting, Eindhoven, the Netherlands. © 2012 Koninklijke Philips Electronics N.V.

in which the gas pressure is very low (0.7 Pa or 7.10^{-6} atm) and high-pressure sodium lamps in which the gas pressure is a factor 10,000–100,000 times higher (10–100 kPa) [2–4]. Because their construction and performance are in many ways different, they are dealt with in two different sections of this entry.

Low-Pressure Sodium Lamps

Low-pressure sodium lamps belong to the group of high-intensity discharge (HID) lamps because they are available in high-light output (and thus high-luminous-intensity) versions. All low-pressure gas discharge lamps have in common the fact that they are long. Low-pressure sodium lamps are highly efficient lamps with a good lifetime but no color rendition at all. Their application is therefore restricted to those situations where color rendering is of no importance, as, for example, on motorways, on railway-marshaling yards, and in some security-lighting situations. Low-pressure sodium lamps are sometimes also referred to as LPS lamps.

Working Principle

The gas discharge principle of low-pressure sodium lamps is similar to that of low-pressure mercury lamps (see that chapter for general details). In low-pressure sodium lamps, the discharge takes place in vaporized sodium. The low-pressure sodium discharge emits monochromatic radiation in the visible range. Therefore, unlike low-pressure mercury lamps, they do not need fluorescent powders to convert the wavelength of the radiation. The monochromatic (single wavelength) radiation is the reason that color rendering is nonexistent. The wavelength of the monochromatic radiation is 589 nm (yellowish light), which is very close to the wavelength for which the eye has its maximum sensitivity (Fig. 1). It is mainly for this reason that the lamp has such an extremely high-luminous efficacy (up to 190 lm/W system efficacy). Like all gas discharge lamps (with very few exceptions), a low-pressure sodium lamp cannot be operated without a ballast to limit the current flowing through it.

Materials and Lamp Construction

The main parts of a low-pressure sodium lamp are (Fig. 2):

High- and Low-Pressure Sodium Lamp,

Fig. 1 Relative eye-sensitivity curve and the monochromatic line of 589 nm of the low-pressure sodium spectrum

High- and Low-Pressure Sodium Lamp,

Fig. 2 Principle parts of a low-pressure sodium-discharge lamp [1]

- Discharge tube
- Fill gas
- Electrodes
- Outer bulb with inner coating
- Lamp cap

Discharge Tube

Just as with the low-pressure mercury, fluorescent tube, and lamp, the power dissipated in the low-pressure sodium lamp largely determines the length of the discharge tube. Especially for the higher wattages (and thus lumen packages), the unfolded length has to be really long. To reduce the actual length of the lamp, the discharge tube of low-pressure sodium lamps is therefore always U shaped. Nevertheless, the highest lumen packages still require a lamp length of about 1.2 m. The U-shaped discharge tube is made of sodium-resistant glass and contains a number of small dimples, or hollows, where the sodium is deposited as a liquid during manufacture. After ignition, the discharge first takes place through the inert gas mixture. As the temperature in the tube gradually increases, some of the sodium in the dimples vaporizes and takes over the discharge, which then emits the monochromatic radiation. At switch-off, the sodium condenses and again collects at the dimples, these being the coldest spots in the tube. Without the dimples, the sodium would, after some switch-on switch-off cycles, gradually condense along the whole inner tube wall, decreasing light transmission considerably.

Fill Gas

The inert gas mixture of neon and argon, called the “Penning mixture,” acts as a starting gas and buffer gas (to protect the electrodes). During start-up, the discharge only takes place in this gas, which is why a low-pressure sodium lamp radiates deep-red light for some 10 min during start-up (Fig. 3).

Electrodes

Most modern low-pressure sodium lamps have cold-start electrodes. These consist of a triple-coiled tungsten wire so that they can hold a large quantity of emitter material.

High- and Low-Pressure Sodium Lamp, Fig. 3 Immediately after switch-on, a low-pressure sodium lamp emits just a little reddish light, which gradually changes to the familiar yellow sodium light when the lamp has fully warmed up [1]

Outer Bulb

The optimum sodium-vapor pressure is reached when the temperature of the wall of the discharge tube is maintained at 260 °C. To reach this temperature efficiently, the U-shaped discharge tube is contained in an evacuated outer-glass tube. To further increase the thermal insulation, this outer-glass tube is coated on its inner surface with an interference layer that reflects infrared radiation but transmits visible radiation. In this way, most of the heat radiation is reflected back into the discharge tube, so maintaining the tube at the desired temperature, while visible radiation is transmitted through the layer. Early low-pressure sodium lamps did not have an integrated outer bulb with infrared reflecting coating. They used a separate double-wall evacuated tube (“thermos bottle”) which was reused after the failure of the gas discharge tube at the end of its life (Fig. 4).

Apart from the dimples, the bend of the U-shaped discharge tube also forms a cold spot

High- and Low-Pressure Sodium Lamp, Fig. 4 Immediately after switch-on, a low-pressure sodium lamp emits just a little reddish light, which gradually changes to the familiar yellow sodium light when the lamp has fully warmed up

where sodium can condense and accumulate. The bend is therefore insulated by a heat-reflecting metal cap.

Lamp Cap

All low-pressure sodium lamps are provided with a bayonet-type lamp cap. This allows the discharge tube to be accurately positioned. This is critical because the light distribution of a low-pressure sodium luminaire is dependent on the position of the U-shaped discharge tube.

Properties

Energy Balance

A low-pressure sodium lamp emits approximately 40% of the input power in the form of visible radiation. This is the highest percentage of all gas discharge lamps. The remaining part of the input power is lost in the form of heat.

System Luminous Efficacy

The luminous efficacy of the system is strongly dependent on the wattage of the lamp and ranges from 70 to 190 lm/W, for low and high wattages, respectively.

Lumen-Package Range

Low-pressure sodium lamps are available in the range from approximately 2,000 to 30,000 lm (corresponding wattage range, 18–180 W).

Color Characteristics

As mentioned before, low-pressure sodium lamps emit monochromatic light in the yellowish part of the spectrum (Fig. 5). Color rendering is therefore nonexistent ($R_a = 0$). The correlated color temperature is around 1,700 K.

Lamp Life

Apart from the usual cause of failure in gas discharge lamps (viz., electrode emitter exhaustion), low-pressure sodium lamps may also fail because of cracks or leaks in the long discharge tube or outer bulb. This may especially be the case in environments where there are strong vibrations as, for example, may occur in poorly designed road-lighting luminaires during strong winds. Leakage in the outer bulb disrupts the thermal isolation, which in turn means that not enough sodium will vaporize. As a consequence, the discharge will take place in the starting-gas mixture, so emitting only the corresponding deep-red light. Economic lamp life is around 12,000 h (based on a 20% mortality rate). Some versions make use of special getter material to maintain a high vacuum, resulting in fewer failures during the economic life of the lamp: the economic lamp lifetime is about 15,000 h (again, mortality rate of 20%).

Lamp-Lumen Depreciation

Lumen depreciation occurs through blackening of the discharge tube by scattering of the emitter material of the electrodes and by discoloration of the glass caused by the sodium. Depending on the type of control gear used, these effects are partially counteracted by a slow and gradual increase in the power dissipated in the lamp.

Burning Position

Electrodes and lead-in wires coming into contact with condensed sodium can eventually suffer damage. To prevent this from happening, low-pressure sodium lamps have restrictions as to their burning position. Base-down burning positions, in particular, have to be avoided. The restrictions are less critical for lower-wattage (viz., smaller) lamps, simply because they contain less sodium.

High- and Low-Pressure Sodium Lamp, Fig. 5 Spectral energy distribution of low-pressure sodium lamps [1]

Run-Up and Reignition

As has already been explained, the sodium needs time to vaporize while the discharge takes place in the starting-gas mixture. The warming-up process takes about 10 min. Nearly all low-pressure sodium lamps reignite immediately. The exceptions are the highest wattage lamps (131 and 180 W), which restrike after 10 min.

Dimming

Low-pressure sodium lamps cannot be dimmed. Dimming would decrease the lamp temperature so that not enough sodium would remain in the vapor state to maintain the sodium discharge.

Ambient-Temperature Sensitivity

The excellent thermal insulation afforded by the outer bulb ensures that lamp performance is almost independent of ambient temperature. Also, thanks to the starting-gas mixture, starting too is almost independent of ambient temperature.

Mains-Voltage Variations

The variations in lamp current and lamp voltage as a consequence of a change in mains supply voltage tend to cancel each other out, the net result being that the lamp wattage and, to a certain extent, the luminous flux remain practically constant over a wide range.

Product Range

Low-pressure sodium lamps are available in two versions, each with a different balance between

efficacy and lumen output. There is a high-lumen-output version with a 10–15% lower efficacy and a high-efficacy version with a 20% lower lumen output, respectively. The high-efficacy lamps can be operated on HF electronic control gear, which further increases their efficacy by between 15% and 35%. The length of low-pressure sodium lamp increases considerably with wattage: The 18 W version (the lowest wattage available) has a length of 22 cm, while the longest lamps (131 and 180 W versions) have a length of 112 cm.

High-Pressure Sodium Lamps

High-pressure sodium gas discharge lamps as well as low-pressure sodium lamps belong to the group of HID lamps because they are available in high-light output (and thus high-luminous-intensity) versions. High-pressure sodium lamps are also referred to as HPS lamps. High-pressure sodium lamps, in common with all high-pressure discharge lamps, are relatively compact. By increasing the vapor pressure in a sodium lamp, the color rendering improves and the color appearance changes from yellow to yellow-white, albeit at the cost of a decrease in efficacy. However, the resulting efficacy is more than double that of a high-pressure mercury lamp. At its introduction in the late 1960s, a very efficient alternative was thus obtained for the many high-pressure mercury lamps employed at that time in

High- and Low-Pressure Sodium Lamp,

Fig. 6 Effect of sodium-vapor pressure on the spectral power distribution of different sodium gas discharge lamps [1]

H

road lighting. Today, road-lighting installations all over the world very often use high-pressure sodium lamps, although for some installations LED solutions have become an alternative.

By further increasing the sodium pressure, the color quality of the light improves to such an extent that the light becomes real white. These so-called white high-pressure sodium lamps have a lower efficacy but sometimes offer an acceptable alternative to halogen and compact metal halide lamps for accent lighting.

Working Principle

It has been shown that with low-pressure sodium lamps at the low working pressure of that discharge, a single, monochromatic line of light at a wavelength of 589 nm is emitted. With increasing pressure, the radiation in the core of the discharge is absorbed by the cooler surrounding gas and reemitted in the form of radiation not of the 589 nm line but with wavelengths slightly smaller and slightly larger than 589 nm. So, the 589 nm line gradually disappears (called self-absorption), while in the wavelength area to the left and right of that value, more and more light is emitted (broadening of the spectrum). The

phenomenon of self-absorption and spectrum broadening is illustrated in Fig. 6, which shows examples of sodium lamps with different operating vapor pressures. The phenomenon is accompanied by a loss of efficacy. At the operating pressure of a standard high-pressure sodium lamp, the lamp has a yellow-white color appearance (2,000 K) and a moderate color-rendering index R_a of approximately 25 at an efficacy, for the higher wattages, of some 140 lm/W. With further increase in operating pressure, the same process continues, viz., widening of the spectrum at the cost of efficacy. With lamps that operate at a four-times-higher pressure, the color rendering improves to “fairly good” ($R_a = 65$) at an efficacy of around 90 lm/W. A version with an operating pressure ten times higher than that of the standard high-pressure sodium lamp is also produced: white HPS. This version has an R_a of 80 and radiates white light with a color temperature of 2,500 K at an efficacy of around 45 lm/W.

Materials and Construction

The main parts of a high-pressure sodium lamp are (Fig. 7):

High- and Low-Pressure Sodium Lamp,

Fig. 7 Main parts of a high-pressure sodium lamp (e.g., tubular version) [1]

- Discharge tube
- Fill gas
- Outer bulb
- Electrodes
- Lamp caps
- Getter

Discharge Tube

Sodium at high temperatures has the tendency to migrate slowly through quartz. Quartz can therefore not be used as material for discharge tubes of high-pressure sodium lamps. Discharge tubes made of ceramic material withstand sodium at very high operating temperatures. This is why, right from their introduction in 1966, high-pressure sodium lamps have translucent, tubular-shaped, ceramic discharge tubes. Since the ceramic tube is produced by sintering minuscule aluminum-oxide particles, one cannot look straight through the wall, although the light transmittance is more than 90% (translucent instead of transparent material).

Fill Gas

Sodium is introduced into the gas discharge tube as a sodium-mercury amalgam composition, which partially vaporizes when the lamp reaches its operating temperature. The sodium vapor is responsible for excitation and subsequent light radiation, while the mercury gas acts to regulate the voltage of the lamp and reduces thermal losses (buffer gas). The starter gas commonly added is xenon. An exception to this is found in the case of low-wattage lamps, which have a built-in igniter in the form of a bimetal switch and a neon-argon mixture – the Penning mixture also used in fluorescent lamps – as starting gas. By increasing the pressure of the starting-gas xenon, the luminous efficacy of the lamp increases by about 20%.

However, to ensure proper ignition at this higher starting-gas pressure, an auxiliary ignition wire has to be added very close to the discharge tube. Some versions of high-pressure sodium lamps, therefore, have an internal ignition strip (see Fig. 7). From an environmental point of view, it can be desirable to have high-pressure sodium lamps that do not contain mercury. Such lamps are, in fact, available. In these mercury-free high-pressure sodium lamps, xenon is used not only as a starting gas but also as the buffer gas that regulates the voltage and reduces thermal losses.

Electrodes

The electrodes employed in high-pressure sodium lamps are basically the same as those found in high-pressure mercury lamps. They consist of a core of tungsten rod with a tungsten coil (impregnated with emissive material) wound around it.

Outer Bulb

To thermally insulate the gas discharge tube and to protect its components from oxidation, an outer bulb is employed. The outer bulb of standard high-pressure sodium lamps is either ovoid or tubular (T version) in shape (Fig. 8). The internal wall of the ovoid bulb is usually coated with a diffusing powder. The coated versions were introduced so as to obtain the same light-emitting area as in regular ovoid, fluorescent-powder-coated, high-pressure mercury lamps. In this way, the coated ovoid high-pressure sodium lamps can be used with the same luminaire optics as those developed for high-pressure mercury lamps. This was especially important at the original introduction of high-pressure sodium lamps when they were replacing many existing high-pressure mercury lamps that were then a standard in many

High- and Low-Pressure Sodium Lamp,

Fig. 8 Different outer bulbs and lamp caps of high-pressure sodium lamps

road-lighting installations. Note that the coating in high-pressure sodium lamps is of the diffusing, nonfluorescent type. Since high-pressure sodium lamps produce practically no UV radiation, there is no point in using fluorescent powder. White high-pressure sodium lamps are usually only available in the tubular form. The glass used for the outer bulb of high-pressure sodium lamps for wattages of more than 100 W is hard glass.

Lamp Caps

The lamp caps employed for standard high-pressure sodium lamps are of the Edison screw type. The white high-pressure sodium lamps have a special bi-pin cap to ensure exact positioning in a luminaire.

Getter

During the process in which the lamp is evacuated, it is impossible to remove all traces of air and water vapor. During the operation of the lamp, minuscule particles evaporate from the glass and metals in the tube. All these traces would lead to an unacceptably short life. To remove them a getter is added that absorbs these traces. The getter is usually in the form of a small piece of solid material (see Fig. 7).

Properties

Energy Balance

Some 30% of the input power of a middle-range type of high-pressure sodium lamp is emitted in the form of visible radiation. Compare this with

the 40% of low-pressure sodium lamps and 17% of high-pressure mercury lamps.

System Luminous Efficacy

The efficacy of the compact white high-pressure sodium lamp varies between approximately 30 and 45 lm/W. The high-pressure sodium lamp with a color-rendering index of 60 has an efficacy between 75 and 90 lm/W, and the standard high-pressure sodium lamps (with R_a around 25) has an efficacy between some 80 and 140 lm/W. The higher the wattage, the higher the efficacy.

Lumen-Package Range

Compact white high-pressure sodium lamps are available in lumen packages from some 1,500 to 5,000 lm (corresponding wattage range of 35–100 W). Standard high-pressure sodium lamps are being produced in the approximate range of 4,000–150,000 lm (corresponding wattage range of 50–1,000 W).

Color Characteristics

As with all gas discharge lamps, the high-pressure sodium lamp spectrum is discontinuous. Figures 9, 10, and 11 show the spectra of a standard high-pressure sodium lamp, a color improved lamp, and a white lamp. The color temperature of these versions ranges from 2,000 to 2,500 K and the color-rendering index from 25 to 80. Since the spectrum of all versions is relatively strong in the red wavelength area, the rendition of human faces is often experienced as being somewhat flattering. Of course, for indoor lighting, the

High- and Low-Pressure Sodium Lamp, Fig. 9 Spectral energy distribution of a standard high-pressure sodium lamp: T_k 2,000 K and R_a 25 [1]

High- and Low-Pressure Sodium Lamp, Fig. 10 Spectral energy distribution of a color improved high-pressure sodium lamp: T_k 2,150 K and R_a 65 [1]

High- and Low-Pressure Sodium Lamp, Fig. 11 Spectral energy distribution of a white high-pressure sodium lamp: T_k 2,500 K and R_a 80 [1]

color rendering of the standard high-pressure sodium lamp is far from adequate. For road lighting, it is experienced as being acceptable.

Lamp Life

The lamp voltage of a high-pressure sodium lamp increases gradually with life. The chief cause of lamp failure is that the lamp voltage rises higher than the voltage output of the ballast, causing the lamp to extinguish. When this happens, the lamp cools down, and the pressure in the lamp decreases so that the igniter can ignite the lamp again. After some minutes, the lamp voltage again increases too much, and the lamp extinguishes again. So, the usual end of life of a high-pressure sodium lamp is accompanied by this so-called cycling effect. For those situations where this on-off cycling might be disturbing or would damage the ballast, special “self-stopping” gear is available that stops igniting the lamp once the high voltage at the end of life is reached.

Standard high-pressure sodium lamps have an economic life of up to some 20,000 h (20% mortality). The lifetime of white high-pressure sodium lamps is not determined by the moment of actual failure of the lamps but by the onset of too large a color shift of the light, which is caused by the gradual increase of lamp voltage. To substantially increase their lifetime, white high-pressure sodium lamps, therefore, employ an electronic voltage stabilizer integrated into their control gear. The economic lifetime of compact white high-pressure sodium lamps, depending on type, lies between some 8,000 and 12,000 h (based on a 20% too-large color shift).

Lamp-Lumen Depreciation

For the compact white lamps, lumen-depreciation values vary between some 20% and 25% (after 10,000 h). The standard high-pressure sodium lamps have a much smaller lumen depreciation of between approximately 5% and 10% (after 20,000 h).

Run-Up and Reignition

The high-pressure sodium lamp must be ignited by a high-voltage pulse, typically 1.8–5 kV. After

ignition, the color of the light is initially white (discharge in the starting gas), changing to yellowish after some 20 s as the sodium amalgam gradually vaporizes and the vapor pressure rises; until after some 3–5 min, the nominal pressure and full light output are reached. The reignition of the hot lamp requires the lamp to cool down for about 1 min to allow the pressure to decrease to a point where the ignition pulse can again ionize the sodium atoms.

Dimming

All high-pressure sodium lamps can be dimmed to a certain extent, depending on the type of dimming equipment used. Lower wattages (100–150 W) can be dimmed with special electronic gear, which allows for dimming to 20%. Higher lamp wattages can be dimmed by including an extra inductive coil (ballast) in the ballast circuit. Lamp color remains virtually constant and lifetime is not affected.

Ambient-Temperature Sensitivity

The behavior of high-pressure sodium lamps during temperature variations differs from that of other discharge lamps because of the excess of amalgam used in the lamp. Although the outer bulb offers some degree of thermal isolation, the lamp manufacturer's specifications should be followed in the design of luminaires as far as its effect on lamp temperature is concerned.

Mains-Voltage Variation

A 5% mains-voltage variation has a 15% effect on the light output of high-pressure sodium lamps. The same 5% mains-voltage variation has a 5% effect on lamp voltage.

Product Range

As shown, high-pressure sodium lamps are available in three basic types: standard high-pressure sodium, an improved color version of high-pressure sodium, and a compact, white-light, high-pressure sodium lamp. The standard high-pressure sodium lamp is available in two forms: the standard one and an extra-high-efficacy version (with internal ignition strip). Most high-

pressure sodium lamps contain a tiny quantity of mercury, but there is also a version that is entirely free of mercury.

For ease of replacement of high-pressure mercury lamps in existing installations with more efficient high-pressure sodium types, a special type of high-pressure sodium lamp has been developed. This type uses a neon-argon (Penning) mixture as starting gas and is fitted with an ignition coil surrounding the discharge tube. These features allow the lamp to be operated on a standard high-pressure mercury-lamp ballast.

Definition

High dynamic range imaging (HDRI or HDR) is a collection of hardware and software technologies that allow the capture, processing, and display of image and video content containing a wide range of intensities between the darkest and brightest areas of an image. Lighting conditions in both natural and man-made environments can range from starlight to artificial illumination to bright sunlight. Traditional imaging techniques typically store information using 8 bits per pixel for each channel, allowing for 256 distinct steps per channel. Consequently, they can only represent a narrow range of this illumination, often resulting in over- or undersaturated regions in the image. In contrast, HDR technologies represent image content using a higher precision (10 or 12 bits, or floating-point numbers) and thus both allow for a much larger number of intensity steps to be encoded, reducing the distance between consecutive steps in image intensity.

Overview

Natural environments contain a vast range of illumination that extends from bright sunlight to starlight. In fact, lighting conditions in natural scenes can extend over more than 14 orders of magnitude. Human eyes are not able to perceive this enormous range simultaneously, but mechanisms in the visual system allow adaptation to the prevailing lighting conditions and surroundings. A recent study has evaluated the simultaneous range of the human visual system under extended luminance levels and has found that under specific circumstances, it can reach (and theoretically exceed) 3.7 orders of magnitude [1].

Traditionally, digital images are stored using 8 bits per pixel to represent the values for each of the three color channels, allowing for 256 distinct levels between the darkest and brightest value within each channel. Consequently, standard imaging techniques can capture and store roughly 2 orders of magnitude between black and white, separated by distinct steps. Any information exceeding the available range appears over- or

underexposed, while values between intensity levels are mapped to one of the 256 available levels, introducing steps into smooth gradients – a process known as quantization.

This is a familiar problem for photographers, as many cases exist where this range cannot adequately capture the full scene. For instance, when capturing the interior of a room, if there is a window with bright sunlight outdoors, the region covered by that window would be significantly brighter than the interior. The photographer would then have to choose whether to expose for the room interior or the window to be captured correctly, losing the remaining information of the scene. Such a solution could be sufficient in an artistic context; however, when images are intended as a realistic and complete representation of a scene, the photographer's choices and limitations of the equipment can affect the results. Useful information may not be captured or images may include bias, as the photographer needs to select an exposure level. Figure 1 shows two photographs of the same scene exemplifying this problem.

High dynamic range (HDR) imaging is a collection of tools and algorithms that allow the capture, storage, processing, and display of images with a wider dynamic range than that afforded by traditional imaging techniques. High dynamic range images and video content use a higher precision to encode luminance information

relative to the 8-bits per color channel traditionally used in previous formats, collectively referred to as standard dynamic range (SDR). This affords two key advantages: first, a much wider range of illumination information can be encoded. Second, the higher precision used (which can vary from 10- or 12-bits per color channel in video formats to floating point number in image formats) means that HDR images have significantly less quantization.

Imaging Pipeline

The inherent differences between HDR and traditional (SDR) imagery, in addition to allowing more information to be captured and opening up many possibilities in terms of applications, also mean that all stages of an imaging pipeline need to be modified. From the capture of HDR images and video, to encoding and high dynamic range storage solutions, to processing, and finally to display, many existing algorithms make assumptions that do not apply to images and video content with a wider dynamic range.

Capture

To capture the full dynamic range of a scene such as the one shown in Fig. 1, a camera would need to be able to capture both bright and darker areas simultaneously. To achieve this, several solutions

High Dynamic Range Imaging, Fig. 1 Both photographs capture the same scene but using different exposure levels. The foliage and colors of the tree are well exposed in the *left image* but the sky has been overexposed and has no details visible. The *right image* on the other hand shows

the details of the cloudy sky much better but at the expense of most information in the rest of the image. Problems such as these can easily be overcome with the use of high dynamic range technologies

High Dynamic Range Imaging, Fig. 2 An HDR image (here shown tonemapped) constructed by combining the seven exposures shown on the *left*. Each individual exposure cannot fully capture all the detail in the scene

have been proposed. A common approach suitable for still images is what is known as exposure bracketing, where multiple images of the same scene are captured sequentially, with varying exposure times, such that all parts of the scene are correctly represented in at least one exposure. One example of such a series of exposures is shown in Fig. 2.

This approach is often used for obtaining HDR photographs of even extreme scenes; however, as consecutive exposures are taken at slightly different times, fast-changing scenes (e.g., moving people or tree branches) can lead to misaligned exposures or ghosting artifacts, making it less suited to video. Nevertheless, certain video camera manufacturers [2] have employed this technique to a limited extent, optionally combining two exposures for extending the available dynamic range. To counter the temporal issues inherent with exposure sequences, differently exposed versions of the scene can be captured simultaneously using specialized cameras, where multiple sensors record the same scene at different exposure levels through optical systems that split light appropriately [3].

Despite these advances, the ideal solution for high quality video acquisition is using a single sensor. Typically, consumer cameras (such as the ones in smartphones) are limited by cost and physical size constraints, necessitating the use of small sensors that offer limited sensitivity. In contrast, professional cameras can incorporate larger sensors, allowing for an extended dynamic range to be captured with acceptable noise levels. Indeed, many professional cameras offer native HDR capture by making use of current HDR encoding formats (discussed in the following section). Nevertheless, similar capabilities are becoming available in certain digital SLR cameras in recent years (e.g., Sony alpha models offering native HDR video) or even in top-end smartphones (e.g., iPhone 12 Pro Dolby Vision video), democratizing HDR video acquisition.

Alternatively, if the HDR image itself is not required or cannot be displayed, multiple exposures can be directly combined into an SDR image, aiming to preserve as much of the original scene detail as possible while fitting within the more limited dynamic range of the SDR format. This process is known as *exposure fusion* [4] and

is commonly employed in smartphones under the provided “HDR” functionality to provide photographs with more detail, while avoiding to pass through a costly floating point format.

Encoding and Formats

An image or video encoding is defined by the precision it offers and the transfer function that it employs to translate linear luminance values to image intensities. Existing SDR encodings typically use 8 bits per color channel, providing 256 distinct levels. To distribute information in a more efficient manner, a nonlinear transfer function is used, translating scene values to image intensities. Largely motivated by historical reasons relating to the response of phosphors used in CRT television, the transfer function used for SDR imagery takes the form of an exponent with a value of 2.2–2.4.

This encoding, standardized by the ITU [5], has remained prevalent until the development of HDR imaging and video but is not well-suited for content with a wider dynamic range, as consecutive intensity steps are likely to give rise to visible quantization artifacts. To alleviate this issue, HDR formats and encodings, as well as HDR-capable extensions to certain existing formats, have been developed.

Ideally, to represent HDR information in a lossless manner, a linear, floating point representation can be used, as is afforded by well-adopted OpenEXR format [6], with the consequence of

large file sizes. Nevertheless, EXR images are used both in HDR photography and as an intermediate format for film postproduction thanks to their near-lossless nature and the extension possibilities that the format offers. In an effort to reduce storage requirements, but without compromising quality, RGBE formats have been developed (standing for RGB and exponent), where 8 bits are used per color channel, as well as a shared exponent also encoded using 8 bits, which enables the conversion of 8-bit integer intensities to floating point with similar precision as the previously mentioned OpenEXR format. This encoding has been standardized in JPEG-HDR, where the RGB channels contain a tonemapped version of the image, offering the additional advantage of backwards compatibility [7].

In the case of video, although some efforts have been made in developing video formats for linear, floating point content, for example, through modification to MPEG video compression [8], to enable the use of HDR video content in use cases such as broadcasting or video streaming, more compact, integer-based formats are necessary to ensure compatibility with the more restricted hardware that is often found in consumer devices and bandwidth limitations. Several standards have been proposed to that end, defining how videos capturing a wider range of illumination can be encoded and subsequently displayed using integer-based encodings requiring 10 or 12 bits per color channel.

High Dynamic Range Imaging, Fig. 3 Transfer functions map between linear luminance values and digital code values

The most widely adopted formats are described in the ITU-R BT.2100 recommendation [9] and are the PQ format (standing for Perceptual Quantizer), developed by Dolby, and the HLG (Hybrid-log-gamma) encoding, developed by the BBC. Figure 3 shows a comparison of the encoding behavior of these formats relative to the BT.709 encoding used in SDR television and a linear encoding as might be used by the EXR format.

Display

The final stage within an HDR image pipeline is the display of still and video content, which can be achieved in two different ways. A number of display technologies have been developed for achieving extended ranges of illumination. The most common solution combines a spatially varying backlight with an LCD front panel, extending the dynamic range compared to conventional displays both toward the dark and the bright ends of the spectrum. Solutions exist that combine a DLP projector, placed behind an LCD panel [10] or alternatively, a matrix of LED light sources can replace the projector [11]. The latter solution has been adopted by television manufacturers in what is termed LED-backlighting and is commonly used in HDR-capable commercially available TVs. Finally, recent developments in display manufacturing have allowed of OLED displays to attain high enough luminance levels. This, combined with their ability to display true black as pixels can be individually turned off with minimal light leakage, makes them ideal candidates for HDR displays.

Although HDR display technologies are now commercially available, they are still only capable of displaying a fraction of the dynamic range available in nature. As such, to display images of arbitrary dynamic ranges on hardware with more restricted capabilities (including commercially available monitors), algorithms that can compress the range of the image to that of the display are necessary. Many such techniques exist and are known as *tonemapping operators*, which will be discussed in the following section.

Tone Reproduction

Different devices are capable of displaying varying dynamic ranges. To ensure that HDR images and content can be displayed on display devices with a more limited dynamic range, solutions allowing the HDR content to be mapped to the capabilities of a particular display are necessary. Since the output of such a mapping should still be useful for visual consumption, the form of this mapping is an important consideration.

In the simplest scenario, one could linearly scale an HDR image to the given display range. Such a solution though would not be adequate for many scenes. Luminance values in HDR images are not linearly distributed across the available range. Instead, the distribution of luminance values in HDR imagery is highly kurtotic: sources and highlights only cover a small number of pixels in the image but are significantly brighter than the majority of the scene, while most pixels represent a relatively small range of intensities. In practice, the consequence of this is that a nonlinear mapping is necessary to ensure that sufficient detail in the scene remains visible.

The aim of tonemapping techniques can then be seen as the compression of the range of an HDR image such that it can be displayed on devices of a lower dynamic range, while preserving the visible detail in the scene. Often, this is also combined with quantization step, transitioning from linear floating point values to encoded, integer intensity values. Compressing the dynamic range of an image leads inevitably to the loss of some information. Consequently, tonemapping operators (TMOs) need to decide which information to keep and which to discard. The human visual system faces a similar challenge, as it is only capable of seeing a considerably smaller range than that available in nature. It should not come as a surprise then that dynamic range reduction is often inspired by aspects of human vision. Before discussing the different tonemapping techniques and their respective merit, a better understanding of the human eye

and the relevant processes to tone reproduction is necessary.

Perceptual Background

Human eyes are one of the means for sensing the world. Figure 4 shows an annotated cross section of the human eye. Light enters the eye through the pupil, travels through the ocular media, and finally hits the retina. The retina is a layer of neural sensors lining the back of the eye, which transduce light into a signal that is transmitted to the brain. Although several layers of neurons are present at the retina, it is the photoreceptors that are sensitive to light. Specifically, rod photoreceptors are sensitive to low light conditions, while cone photoreceptors are sensitive to brighter conditions.

High Dynamic Range Imaging, Fig. 4 A simplified cross section of the human eye

One of the most important properties of the human visual system with respect to dynamic range reduction is its ability to adapt to a wide range of illumination. This effect is experienced on a daily basis: it is sufficient to walk into a dark room from bright sunlight for the eyes to adjust to see under the new conditions. Effectively, the human visual system adapts to the prevailing lighting conditions so that contrasts in the scene can still be distinguished.

It is not a single process within the human visual system that is responsible for this effect, but rather a combination of factors. One familiar to most is the adjustment of the diameter of the pupil depending on the illumination. Another set of mechanisms occurring in the photoreceptors, which prevents them from saturating while adapting to the enormous range of illumination in nature, is their nonlinear response to illumination. This nonlinearity was first studied by Naka and Rushton [12] and provides a very effective mechanism for the compression of dynamic range. Intensities in the middle of the range lead to approximately logarithmic responses, while as the intensity is increased, the response tails off to a maximum. After that maximum is reached, further increases in intensity will not lead to a corresponding increase in response of the photoreceptors, ensuring that saturation will not occur [13].

Figure 5 shows the nonlinear response of photoreceptors to increasing luminance values, which can be modeled with what is known as the *Naka-Rushton equation*:

High Dynamic Range Imaging, Fig. 5

Photoreceptors respond nonlinearly to increasing luminance levels. The Naka-Rushton equation models this nonlinearity, producing S-shaped curves when plotted in a log-linear scale, known as sigmoid

$$\frac{V}{V_{\max}} = \frac{I^n}{I^n + \sigma(n)} \quad (1)$$

where V is the response at an intensity I , $V_{\max}$ is the peak response at saturation, and σ is the intensity necessary for the half-maximum response. The exponent n controls the slope of the function and is generally reported to be in the range of 0.7–1.0 [13]. This functional form is known as a *sigmoid*, because it forms an S-shaped curve when plotted on log-linear axes. This aspect of light adaptation of the visual system has played an instrumental role in dynamic range compression, which will be discussed in the following section.

Perceptually Motivated Tone Reproduction

Many tonemapping operators use models of photoreceptor adaptation to effectively reduce the dynamic range of input HDR images. Typically, this involves a forward step where the dynamic range of the image is compressed, considering the lighting conditions and appearance of the scene, followed by an inverse step that considers the parameters of the display where the image will be viewed, as shown in Fig. 6. If the forward step is derived from a model of the human visual system, it transforms the image from luminance

values to perceived values, essentially modeling what the original scene would be perceived as if the viewer were present. The reverse step then takes the compressed (now perceived) values back to luminance values, allowing them to be correctly displayed. Note however that many tonemapping operators do not employ the reverse step in order to maximize compression.

To approximate the compression afforded by photoreceptors, several functions have been proposed. At their simplest, linear scaling functions have been shown to be effective if the scaling factor is chosen appropriately, depending on the properties of the image and the intended display. Although such a linear compression scheme can create realistic results in less extreme cases, some information will be clamped for the image to fit within the displayable range. A better approximation of light adaptation behavior of photoreceptors can be achieved using a logarithmic mapping. Further, to better adapt this mapping to the image content, the base of the logarithms can be modified on a per-pixel basis in order to appropriately adjust the compression. More akin to photoreceptor behavior are sigmoid models, which have been used extensively in tone reproduction [14].

High Dynamic Range Imaging, Fig. 6 The typical steps in the tonemapping process

More complete models of photoreceptor physiology and light adaptation have been repeatedly used in the tone reproduction literature, offering perceptually accurate reproductions but at the cost of increased computational complexity and the need of accurate parameters describing the scene and viewing environment. An early and fairly complete model that incorporates luminance, color, and pattern representations to create a perceptually accurate compressed image employs a multi-scale processing scheme [15]. Another notable example that lends itself to HDR compression is the *retinex* model, which considers aspects of both the retina and the brain in order to model complex perceptual phenomena such as color constancy [16].

Multi-scale Tone Reproduction

Features in images occur at different scales, and many tone reproduction techniques employ mechanisms that treat images at multiple scales, improving the appearance of the final result as a different amount of compression can be applied to different features in the image. This ensures that high-contrast features are sufficiently compressed, while local edges (e.g., texture) are not proportionally scaled as that would reduce their visibility. To decompose the image into different scales, a form of edge-preserving filtering is typically used, such as the *bilateral filter* [17]. To improve upon the computational costs and limitations of the bilateral filter, other edge-preserving approaches have been proposed, including the domain transform [18] or the Laplacian pyramid [19].

Display and Viewing-Adaptive Tonemapping

Most tone reproduction algorithms discussed so far aim to compress the range of a given image to a displayable range, but with no consideration of any further properties of the device or the environment where the image will be viewed. Although many detailed appearance models exist that take into account aspects of the environment where the image was captured as well as where and how it will be displayed, such models tend to require additional input that is usually not available in a typical tonemapping setting.

In addition to the parameters of the viewing environment, different display devices offer varying capabilities that need to be considered. Mantiuk et al. formulated tonemapping as an optimization problem that strives to reduce the dynamic range of an image while minimizing the visible distortions that will inevitably be introduced in the process [20]. To detect visible distortions, a model of the human visual system is used, and to ensure that the resulting image is suitable for the target device, a display model is incorporated. Such a scheme allows for images to be tonemapped even for unconventional devices and viewing conditions.

Dynamic Range Expansion

Tonemapping techniques discussed so far compress the dynamic range of images to prepare them for displays with more limited capabilities. With the advent of HDR displays, the inverse problem arises. To fully take advantage of the extended dynamic range available on such a display, it may be desirable to expand the intensity range of traditional image and video content, a process known as *dynamic range expansion* or *inverse tonemapping*. This can be achieved by applying an expansion function to the intensity values of the image to map them to the range of the display. Both nonlinear (such the inverse of Eqs. 2 and 4) [21] and linear schemes have been proposed. Alternatively, an observation that has been exploited in inverse tonemapping is that in many scenes, luminance distribution is highly kurtotic, with most pixels covering a relatively small part of the range, while most dynamic range is allocated to light sources and highlights. To simulate this when expanding the dynamic range of images, bright areas of the image can be enhanced more [22].

To address more varied content, where the goal is not necessarily to recover the luminance distribution of the original real-world scene, several methods propose content-adaptive conversions, where the parameters used in the luminance expansion are determined by analyzing the characteristics of the content [23]. Focusing on the use

case of color-graded content, Bist et al. [24] proposed a style-aware adaptive solution, where the parameters are chosen so that the creative lighting style of the original is preserved as well as possible, as determined through a series of user studies.

A final issue to be considered in dynamic range expansion is that of under- or overexposed areas in the image. Even in a well-exposed image, light sources and highlights are likely clip to white, leading to loss of detail in those areas. When expanding such images, it is desirable to reintroduce some of the lost detail in these areas, which can be achieved through *hallucination* techniques, where overexposed regions are filled in using information from surrounding areas of the image [25]. More recently, the predictive power of deep learning approaches has been put to use for reconstructing the dynamic range of images in this context, focusing in particular on overexposed areas [26].

Commercial Solutions

Despite the extensive research in the field of dynamic range management, and the wealth of different approaches proposed in the literature, few commercial solutions are available for tackling the challenge of tone compression and expansion in professional video pipelines. Given the temporal constraints of real-time workflows (as would be the case in broadcasting, for instance) and the restricted hardware that might be encountered in embedded electronics (TVs, set-top boxes, cameras, etc.), complex, multi-scale filtering approaches are rarely implementable.

Further, the majority of existing solutions discussed above consider HDR imagery with a very wide dynamic range. In contrast, most media production workflows utilize HDR in a more conservative manner, with the goal of better preserving the highlights in the image, but without significantly increasing the average image luminance. Consequently, somewhat different approaches have been adopted in this kind of use case.

Several dynamic range mapping approaches are described in the ITU-R BT.2446 report [27]. Concretely, most existing luminance mappings used in production take the form of predefined look-up tables (LUTs) describing how the input

luminance information should be mapped, and consider specific reference levels. Alternatively, some content-adaptive solutions have been proposed commercially as discussed previously to ensure that the creative style of images is preserved despite changes in dynamic range.

Color Management in Tone Reproduction

Most of the tone reproduction operators discussed so far operate on a luminance representation of the image. Typically, a tonemapping operator will compress the world luminance L_w , which is computed from the RGB values in the image, to a display luminance L_d . To form the resulting tonemapped image, the RGB values will have to be scaled in such a way that the ratio between the three channels is kept the same before and after the compression. This can be achieved as follows:

$$\begin{bmatrix} R_d \\ G_d \\ B_d \end{bmatrix} = \begin{bmatrix} L_d \frac{R_w}{L_w} \\ L_d \frac{G_w}{L_w} \\ L_d \frac{B_w}{L_w} \end{bmatrix} \quad (2)$$

This process preserves the ratios between channels, but it is not sufficient to maintain the appearance of colors in the image. Saturation depends on both chromatic information and intensity values, and thus, luminance compression through tonemapping can lead to an oversaturated appearance (or undersaturated in the case of dynamic range expansion). To control the saturation of the tonemapped image, an exponent s can be used when reconstructing the three color channels from the adjusted luminance [28] (here shown only for the red channel):

$$R_d = L_d \left(\frac{R_w}{L_w} \right)^s \quad (3)$$

Although this approach is frequently employed as part of tonemapping operators, it may cause undesirable luminance shifts. Alternatively, the

three channels can be recomputed from the adjusted luminance as follows:

$$R_d = L_d \left(\left(\frac{R_w}{L_w} - 1.0 \right) s + 1.0 \right) \quad (4)$$

Both solutions offer simple saturation control but rely on manual selection for the parameter s . To automate the parameter selection for global tonemapping operators, a series of psychophysical experiments has derived a link between the gradient of tonemapping curve and the saturation parameter for both correction formulas [29]. An alternative, more general approach was proposed in Ref. [30], which can be applied without any knowledge of the tonemapping being necessary.

If additional information is available about both the image itself and the target viewing environment and device, accurate treatment of luminance in conjunction with color is possible using *color appearance models* (CAMs). Most such models are designed with accurate color reproduction as their primary aim and operate on a limited range of intensities. The increasing availability of HDR devices and content, however, has led to the development of several models capable of handling content of extended dynamic ranges, effectively combining tone reproduction and color appearance modeling. In contrast to the operators discussed so far, CAMs process each channel of the image separately rather than only compress luminance [31]. Typically, such models employ both a forward and an inverse step, taking the scene and viewing parameters into account, although it was recently shown that the inverse step may be bypassed, while still accurately reproducing color appearance [32].

High Pressure Mercury Lamp

Wout van Bommel

van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

High-pressure mercury gas-discharge lamp;
High-pressure mercury-vapor lamp

Definition

A lamp that produces light as a result of an electrical discharge, generated between two electrodes, in a high-pressure mercury vapor that is contained in a transparent bulb. In some versions, fluorescent powder is applied that converts the ultraviolet part, which is emitted together with visible light, into visible light to improve the color quality of the light.

Modified and reproduced from [1] by permission of Philips Lighting, Eindhoven, The Netherlands. © 2012 Koninklijke Philips Electronics N.V.

High-Pressure Mercury Gas-Discharge Lamps

High-pressure mercury lamps belong to the group of high-intensity discharge (HID) lamps because they are available in high lumen output (and thus high luminous intensity) versions. High-pressure mercury lamps are available in versions where the discharge takes place in vaporized mercury only and in versions in which metal halides are added so that the discharge takes place in mercury vapor and in vaporized metals from the metal-halide components [2, 3]. These latter types are called metal-halide lamps. Given the unique operating principle and construction of metal-halide lamps, they are dealt with in a separate entry “metal-halide lamp.”

High-pressure mercury lamps, like all high-pressure discharge lamps, are compact compared to low-pressure discharge lamps. They have moderate efficacy and moderate color rendering. With their cool-white light, they were, until the 1970s of the last century, extensively used in road lighting, especially in built-up areas. Since the introduction of the more efficient high-pressure sodium lamps in the late 1960s, these lamps have in many cases replaced high-pressure mercury lamps.

Working Principle

The gas-discharge principle of high-pressure mercury lamps is similar to that of all other gas-discharge lamps. In high-pressure mercury lamps, the discharge takes place in vaporized mercury at a pressure of around 10^6 Pa (10 atm). The spectrum of the radiation is a line spectrum with emissions in the long-wave UV region and in the visible region at the yellow, green, blue, and violet wavelengths. The lamp without fluorescent powder lacks red in its spectrum and has a bluish-white color appearance and very poor color rendering. In most high-pressure mercury lamps, fluorescent powders are used to improve the color quality by converting a large part of the (small) UV component into visible radiation, predominantly in the red end of the spectrum. The result is cool-white light of moderate color rendering and improved efficacy. Like all gas-

High Pressure Mercury Lamp, Fig. 1 Principle parts of a high-pressure mercury gas-discharge lamp [1]

H

discharge lamps (with very few exceptions), a high-pressure mercury lamp cannot be operated without a ballast to limit the current flowing through it.

Materials and Construction

The main parts of a high-pressure mercury lamp are (Fig. 1):

- Discharge tube
- Fill gas
- Electrodes
- Outer bulb (often with fluorescent coating)
- Lamp cap

Discharge Tube

In view of the high operating temperature, quartz is used for the discharge tube because it has a higher melting temperature than glass.

Fill Gas

The discharge tube contains a small quantity of mercury and an inert gas filling.

Electrodes

The main electrodes consist of a core of tungsten rod with a tungsten coil (impregnated with emissive material) wound around it. To aid starting, an ordinary high-pressure mercury lamp has not only an inert gas but also an auxiliary electrode.

Because of this, an ordinary mercury lamp does not need an external igniter. The auxiliary electrode simply consists of a tungsten wire positioned very close to one of the main electrodes (Fig. 2).

Outer Bulb

An outer bulb (usually ovoid in shape) with an inert gas filling isolates the gas-discharge tube so that changes in ambient temperature have no influence on its proper functioning. It also protects the lamp components from corrosion at the high operating temperatures involved. For the smaller wattage lamps, with their lower operating temperatures, ordinary glass is used, while for the other types, hard glass is used.

Fluorescent Powder

As has already been mentioned, high-pressure mercury lamps usually employ fluorescent powder to improve the color quality of the light emitted. The powder is provided as a coating on the inner surface of the outer bulb. Different fluorescent coatings are used to obtain different lamp types with different color qualities and lamp efficacies.

High Pressure Mercury Lamp,

Fig. 2 Discharge tube showing the auxiliary electrode and two main electrodes

High Pressure Mercury Lamp,

Fig. 3 Spectral energy distribution of a high-pressure mercury lamp with fluorescent powder [1]

Lamp Cap

Lamp caps are of the Edison screw type, with the wattage of the lamp determining their size (E27 and E40).

Properties

Energy Balance

Approximately 17% of the input power is emitted in the form of visible radiation. Compare this with the 28% of a tubular fluorescent lamp and the 30% of a high-pressure sodium lamp.

Luminous Efficacy

Luminous efficacy varies with lamp wattage and with the color quality of the lamp from some 35–60 lm/W.

Lumen Package Range

High-pressure mercury lamps are produced in lumen packages between some 2,000 and 60,000 lm (corresponding wattages between 50 and 1,000 W).

Color Characteristics

As has already been mentioned, high-pressure mercury lamps have a line spectrum (Fig. 3).

High Pressure Mercury Lamp,

Fig. 4 Different wattage ovoid and reflector type of high-pressure mercury lamps [1]

High Pressure Mercury Lamp,

Fig. 5 Blended light lamp with high-pressure mercury gas-discharge tube and tungsten incandescent filament combined in one outer bulb. To show the construction, a clear lamp is shown, although most blended light lamps use a fluorescent powder coating on the interior of the outer bulb [1]

H

The two lines in the red part of the spectrum are obtained by conversion of ultraviolet radiation by the fluorescent powder. The color characteristics are dependent on the composition and quality of the fluorescent powders used. Different compositions and qualities are used to produce lamps with color temperatures between some 3,500 and 4,500 K, with color rendering index (R_a) values of around 60 for high-quality versions and around 40 for ordinary versions.

Lamp Life

As with most gas-discharge lamps, lamp life is determined by emitter exhaustion of the electrodes. Economic life varies according to the type between 10,000 and 15,000 h (20% mortality).

Lamp Lumen Depreciation

Lamp lumen depreciation is caused by evaporation and scattering of electrode material (lamp

blackening) and by the gradual decrease in the activity of the fluorescent powder. The point at which 20% lumen depreciation occurs lies at around 10,000–15,000 h.

Run-Up and Reignition

The run-up time of a high-pressure mercury lamp to its full temperature and corresponding nominal mercury pressure is some 4 min. The hot lamp will not restart until it has cooled sufficiently to lower the vapor pressure to the point at which restrike with the voltage available is possible. The reignition time is in the order of 5 min.

Dimming

High-pressure mercury lamps cannot be dimmed.

Mains Voltage Variations

A 5% variation in the mains voltage changes both lamp current and light output by 10%.

Overvoltage decreases the lamp life and increases lamp depreciation because of the correspondingly higher current.

Product Range

High-pressure mercury lamps are available in an ordinary version with poor color rendering (R_a of around 40) and in so-called comfort versions with an improved color rendering of around 60. The bulb is ovoid in shape and increases in size, with an increase in wattage (Fig. 4). Versions without fluorescent powder are hardly, anymore, produced. Reflector lamp versions are produced with a cone-shaped outer bulb and an internally reflective coating on the front (Fig. 4, right).

There is one version of the high-pressure mercury lamp, the “blended light lamp,” that does not need an external ballast. The ballast has simply been built into the lamp itself in the form of a tungsten filament (Fig. 5). The lamp can be connected directly to the mains. The light from the mercury discharge and that from the heated filament blend together (hence the name blended light lamp). The color characteristics of this lamp are therefore better than those of an ordinary high-pressure mercury lamp, but this comes at the cost of a considerably lower efficacy.

Human-Centric Lighting

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Integrative lighting](#)

Definition

Human-centric lighting (HCL Lighting) that takes both the beneficial visual and nonvisual biological effects of lighting into account. CIE defined in a draft international standard the term “Integrative Lighting” with the same meaning as human-centric lighting: “lighting specifically designed to produce a beneficial physiological and/or psychological effect upon humans, including visual and non-visual effects” [1].

Image and Non-Image Forming Processes in the Eye

An image forming process in the eye produces visual effects of light. Other processes produce nonvisual biological effects of light. They are, therefore, sometimes referred to as “non-image forming effects of light” (in short, NIF effects of light). Today, most lighting standards in the world are developed so that the lighting installation provides proper visual effects seen from both a point of view of visual performance and visual satisfaction (visual comfort). The non-image forming effects influence the way our body “operates” and therefore, influence our health and well-being (see the entries ► [“Nonvisual Lighting Effects and Their Impact on Health and Well-Being,”](#) ► [“Circadian Rhythms,”](#) and ► [“Sleep, Alertness, and Light”](#) of this Encyclopedia). Only if the lighting designer succeeds in designing and installing lighting that results in both suitable visual and nonvisual biological effects,

Human-Centric Lighting, Fig. 1 Visual and nonvisual biological effects of lighting and benefits of good lighting

optimised visual performance and comfort, health and well-being may be expected to be obtained. In the context of lighting for work, this, in turn, propagates better work performance, fewer errors, improved safety, and lower absenteeism. Figure 1 sketches the relationship between the different effects of lighting and shows the benefits to be expected from good lighting for work. Good human-centric lighting can have a positive influence on work performance, errors, safety, accidents, and absenteeism.

Circadian and Direct Photobiological Effects of Light

Non-image forming effects of light consist of circadian and direct photobiological effects. Daily or circadian bodily rhythms, a fundamental property of human life, are synchronized by the natural 24-h dark-light rhythm. Light and darkness have a long-term effect on circadian bodily rhythms [2–6]. A correct circadian rhythm ensures, among others, that melatonin, the hormone that increases sleepiness, has its maximum concentration slightly after midnight, while cortisol, the hormone providing energy to the body, has its maximum in the morning. Light received up to a few days before can influence the circadian rhythm. As such, it has a long-term effect. Light can, however, also have short-term, direct effects within a short time after being exposed to light. The effects usually disappear shortly after the light exposure stops. Light, both at day and night, can acutely decrease sleepiness and improve alertness [7–9]. The increase of alertness, in turn, has positive consequences for

performance. Both effects of light are discussed in more detail in the entries ► [“Nonvisual Lighting Effects and Their Impact on Health and Well-Being,”](#) ► [“Circadian Rhythms,”](#) and ► [“Sleep, Alertness, and Light”](#) of this Encyclopedia.

Dynamic Lighting Scenario for Daytime Work

The state of knowledge of today indicates that for entrainment of the biological clock and for direct photobiological effects (influencing alertness and performance) the bare minimum illuminance at the eye is some 400 to 500 lux. (see the entries ► [“Nonvisual Lighting Effects and Their Impact on Health and Well-Being,”](#) ► [“Circadian Rhythms,”](#) and ► [“Sleep, Alertness, and Light”](#) of this Encyclopedia). This holds for light sources with a correlated color temperature between approximately 3000 and 4000 K. For higher color temperatures, the required value is lower. For values of around 6500 K, the required value can be halved: some 200 to 250 lux. Lamps of 3000 to 4000 K have a melanopic equivalent daylight (D65) factor of some 0.4 to 0.6 and lamps of 6500 K approximately 1.0. These eye illuminances, therefore, correspond to melanopic equivalent daylight (D65) illuminances of approximately 200 to 300 lux.

The nonvisual biological effect of light is not directly governed by the illuminance on the working plane, but by light entering the eye. For the lighting designer, however, it is more convenient to work with illuminances on the horizontal working plane. Converting required illuminances on the eye (for all locations in the space) into an approximate average horizontal illuminance value of the horizontal working plane is thus needed. With the kind of light distributions and layout of luminaires typically used in office and industrial spaces, the average horizontal illuminance at working plane level corresponds to roughly three times the amount of vertical illuminance at eye height. On this basis, Table 1 gives the minimum required average

Human-Centric Lighting, Table 1 Minimum horizontal illuminance on the working plane of office type of spaces. Converted from illuminances at the eye

CCT	E _{eye} (lux)	E _{eye, mel, D65eq} (lux)	E _{hor, av} (lux)
3000–4000 K	500	250	1500
ca. 6500 K	250	250	750

horizontal illuminance values on the working plane.

In most offices and industrial spaces, these lighting levels are not available from daylight entering the premises for those not working close to windows, especially not in wintertime outside the tropical latitudes. In these situations, artificial lighting should take care of the extra lighting required. A lighting scenario which dynamically changes both the lighting level and color enables optimization between energy requirements on the one hand and requirements of visual and nonvisual effects on the other hand.

Figure 2 sketches an example of such a daytime dynamic lighting scenario for a working day starting at 8:00 in the morning and finishing at 17:00.

The morning lighting begins with a horizontal illuminance level of 750 lux and a cool-white color (approx. 6500 K). This situation corresponds to roughly 250 lux melanopic equivalent daylight (D65) illuminance. It helps to entrain the biological clock and evokes direct photobiological effects providing alertness and performance potential. This lighting condition lasts for some 2.5–3 h. After that, the lighting level gradually decreases, and the color gradually turns warmer. By the beginning of the afternoon, around lunchtime, the lighting level reaches its lowest level of 500 lux while the color has its warmest tint (around 3000 to 4000 K). This situation corresponds to roughly 85 lux melanopic equivalent (D65) illuminance. The minimum horizontal lighting level is never lower than 500 lux, being the minimum level recommended for visual performance and comfort. The midday situation of low lighting level and warm color supports relaxation around lunchtime. It also does not work

Human-Centric Lighting, Fig. 2 Example of a dynamic lighting scenario for human-centric lighting in offices (daytime use)

against short naps for those who want to have them. Lunchtime power naps have shown to help to feel revitalized and to improve performance for some 2–3 h in the afternoon [10, 11]. These multiple short naps should last some 3–20 min and be taken well before 15:00 h. The latter, in order not to diminish the sleep pressure, is already building up and required for sleep during the night. A short bright light exposure after lunchtime also has a revitalizing effect [12, 13]. Therefore, a short-lasting (some 30 min) post-lunch rise in light level combined with higher color temperature is included in the scenario of Fig. 2. After the post-lunch rise, the lighting level decreases again while the color temperature gradually returns to 3000 to 4000 K. The absence of bright cool light in the afternoon also avoids interference with the gradual rise of melatonin later in the afternoon or early evening.

The dynamic daytime scenario illustrated in Fig. 2 is based on the bare minimum requirements for everyday office tasks. For difficult visual tasks, the minimum lighting level has to be higher than 500 lux. For challenging tasks with severe consequences in the case of errors, alertness and performance requirements can be extremely high. This, of course, also holds for potentially hazardous conditions in industrial environments. For such tasks or conditions, the lighting level of 750 lux should be increased, and higher correlated color temperatures than 6500 K could be considered.

[Color imaging](#); [Color science](#); [Multispectral imaging](#); [Spectral imaging](#)

Definition

The goal of spectral imaging is to recover radiance and reflectance spectra at each pixel in a scene. The stored hyperspectral information for each pixel refers to data from spectra which is sufficiently well scanned so that to be considered as a continuous spectral signal. Typically, such spectral imaging systems consist of a digital camera coupled to a range of spectrally broadband or narrowband filters. Depending on the number of filters used, spectral systems can be classified into multispectral imaging systems, when a small number of 3–10 filters is used, hyperspectral systems, if the number of filters extends up to

10–100, or ultraspectral, when the number is even greater than 100. If the number of filters is sufficiently large and their bandwidths are sufficiently small, as with a hyperspectral and ultraspectral imaging systems [1–3], spectral data can be recovered exactly.

Overview

Multispectral imaging ordinarily uses a digital charge-coupled device (CCD) camera coupled with colored filters of different spectral bands, ranging from just three components, as in a red-green-blue (RGB) conventional camera, up to hundreds of components, as in a hyperspectral system [3]. If the sensor of the CCD camera is monochrome, a high number of narrowband filters is traditionally used, while if the sensor is the RGB color type broadband filters can be used which makes it possible to work with a significantly reduced number of filters. It is the type of sensor which determines the number of channels in a spectral camera thus allowing a first classification of the different typologies of the acquired spectral images, whether with multi- or hyperspectral imaging. The main application of spectral imaging is in areas where a good or high spatial resolution of the spectral measurement is needed. Traditionally, conventional spectroradiometers are the devices used for spectral measurements which are not only expensive but just allow a spectral measurement of a relatively large area (some 2°–10°) of the scene. This significantly limits the spatial details of the scene to be spectrally characterized. On the other hand, the spectral devices used for acquiring images allow, for example, the measurement of the spectral reflectance of each pixel in the scene (Fig. 1). The hyperspectral techniques used for acquiring images are very important in color imaging because they allow a full spectral reflectance or spectral radiance measurement for each pixel image, thus “preserving” almost the exact colorimetric components of the scene, by just converting this spectral radiance or reflectance to the CIE XYZ tristimulus values [4, 5].

Hyperspectral Imaging, Fig. 1 Rendered scenes (top row) and (bottom row) captured spectra from a commercial Bragg-grating-based hyperspectral imager and a

commercial multispectral camera truePIXA (<https://www.chromasens.de/en>)

Some Basics on Image Acquisition and Spectral Imaging

Image capture devices are used in general to obtain digitized images of real-world scenes by forming a real image of the scene into its sensor plane area. Thus, their purpose is to transform the continuous, wide range, and very detailed real world into a set of flat quantized values, each corresponding to a pixel. For a conventional RGB color image, this process is equivalent to building a stack of three planes (or sets of organized pixels), each one corresponding to the red, green, and blue dimensions. The camera sensor can either be a CCD (charged-coupled device, known as the technology of moving and storing the electron charge) or a CMOS (complementary metal oxide semiconductor, known as the technology used to build a transistor into a semiconductor wafer). Typically, an organized array of small square color filters called a Bayer filter is placed in front of the sensor to allow

color image capture. The raw data from the sensor are fed into the image processor which performs the transformation of the raw data to the quantized three-plane color image. For most color digital cameras, the color is read by placing a mask of colored filters in front of the sensor, and then interpolating the readings of adjacent pixels to get the three RGB values. The fact is that standard color digital cameras never have full-color resolution, as each pixel is obtained by interpolating from adjacent pixels, and this is the cause of some artifacts such as color fringing in the image in some cases. The interpolation procedure also makes the capture process slower. Moreover, the usual practice in color imaging is to modify the natural spectral response of the sensor by placing an infrared-blocking filter to cut-off the higher wavelength response, and also of course the three RGB filters (either in a Bayer arrangement or covering the whole area of the sensor). In the end, the color cameras have three spectral response curves, each

Hyperspectral Imaging, Fig. 2 Illustration about how to store the spatial and spectral information in different hyperspectral imaging systems

corresponding to a red, green, or blue color channel.

A hyperspectral image of n bands (or n channels) with spatial resolution of $(r \times c)$ can be represented as a three-dimensional data cube $\mathbf{C} = [C(x; y; \lambda)]_{(r \times c \times n)}$, where x and y represent the spatial dimensions of the images, and λ represents the spectral dimension; in most cases, the image intensity corresponds to either the spectral radiance or spectral reflectance factor [3, 5, 6]. As can be seen in the next sections, there are many ways of capturing that spectral cube. Some spectral imaging systems need dispersive optics elements (a prism or a single slit) to spectrally decompose the incoming light. Alternatively, other system architectures use a set of a number of optical filters mounted in a filter wheel placed sequentially in front of a monochrome camera. For the purpose of a proper calibration, raw image sequences have to be corrected for noise (e.g., camera dark-current noise and non-uniformity in the sensor array response), stray light, off-axis vignetting, and potential chromatic differences of magnification or translation. The spectral reflectance at each pixel can be estimated by normalizing the aforementioned corrected signals against that obtained from a neutral reference flat-field placed in the captured scene [3, 5]. As

illustrated in Fig. 2, the spectral data collected are stored as a “hypercube” $\mathbf{C}$, which contains spatial data in two dimensions and spectral data along a third dimension for each pixel in the image.

Direct Spectral Measuring Systems

These systems are conventionally known as hyperspectral imaging systems. If the number of channels n is sufficiently large and their bandwidths are sufficiently small, spectral data can be recovered exactly from the data cube $\mathbf{C}$. Thus, these systems require both a huge amount of processing time and a large storage capacity [7]. Such hyperspectral systems in turn can be classified in three main categories, depending on the scanning step introduced along the spectral and spatial dimension: spectral domain scanning systems, spatial domain scanning systems, and snapshot-based systems.

Spectral Domain Systems

These spectral systems scan an image in the spectral domain by separating the light into its spectral components. To this end, they use a monochrome sensor coupled to a set of narrowband filters. To record a complete hyperspectral cube $\mathbf{C}$, several image captures of the scene are needed (one per spectral band), which means that the objects within the scene should remain static. One of the most used narrowband filters used in these types of systems is the liquid crystal tunable filter (LCTF). The LCTF is a tunable interference filter based on the electro-optic effect present in liquid crystals (or crystals). In short, it consists of two polarizers and a variable retarder placed between them, which changes its refraction index when an electrical field (voltage difference) is applied which provokes an electro-optic effect. The LCTF illustrated in Fig. 3 was manufactured by the Varispec series of CRI with a usable wavelength range from 400 to 720 nm, and the optical resolution or bandwidth of the spectral transmittance peaks was from 7 to 20 nm. This device allowed a tuning resolution of 1 nm and thus is equivalent to the use of a large set of narrowband filters. In the case of outdoor hyperspectral

Hyperspectral Imaging, Fig. 3 (Left) CCD monochrome camera coupled with an LCTF placed in front of the lens of the camera; (right) spectral sensitivities of the channels selected in the LCTF [9]

Hyperspectral Imaging, Fig. 4 Working principle of the Specim's Inspector (top row) and (bottom row) example of a scene captured in three spectral bands (from <https://www.specim.fi/>)

imaging, varying daylight illumination has to be taken into account [8, 9].

Spatial Domain Systems

These systems are based on a local scan of the areas of the scene in order to obtain the complete spectral information of each of these areas. The most common configuration to achieve this scan is the use of line-scan CCD sensors which allow a line by line sweep of the scene, resulting in a high spatial resolution. A line-scan camera scans moving objects by repeatedly capturing a single line of pixels at a high frequency. Therefore, these spectral systems act like line scanners which disperse

the polychromatic light emerging from each pixel and separately register each wave length component of each point in the scanned line. One of the most commonly used setups is Specim's Inspector (see Fig. 4) where either the sample or the camera has to be moved to achieve the special scan required. This device is commonly used in the quality inspection industry to monitor the quality of fruit and foodstuffs and for the accurate color classification of the products.

Snapshot-Based Systems

These systems are able to spectrally decompose the incoming light from very small areas of the

scene. Thus, in the sensor array, they receive both bidimensional spatial and spectral information. This is a clear advantage in comparison with other spectral systems but due to the complex pupil and lens arrays used to reimage the dispersed areas of the scene in the sensor, the sensor resolution is poor (around 300×300 pixels) and needs a powerful controlled illumination. These systems are thus mainly used in microscopy [10].

Indirect Spectral Imaging Systems

When a CCD digital color camera is pointed at a surface with a spectral reflectance function $r(x, y; \lambda)$, the response of the n th sensor for pixel (x, y) can be modeled linearly by,

$$C_n(x, y) = \sum_{\lambda=400}^{700} E(x, y; \lambda) r(x, y; \lambda) Q_n(\lambda) \Delta\lambda \quad (1)$$

where $Q_n(\lambda)$ is the spectral sensitivity of the n th sensor and $E(x, y; \lambda)$ is the spectral power distribution of the illumination impinging on the surface. Equation (1) means that if the number of channels n is small, with just a few broadband filters, the spectral recovery, either $r(x, y; \lambda)$ or $E(x, y; \lambda)$, represent an ill-posed problem. Many multispectral-imaging methods exploit the underlying smoothness of signal spectra, with illuminants and spectral reflectances represented by low-dimensional models based on principal component analysis (PCA) or independent component analysis (ICA) [2, 11, 12]. Thus, given a linear model, if the number of PCA (or ICA) coefficients of a particular set of spectra is the same as the number of camera responses (three in the simple trichromatic case), then the spectra can be derived by an inverse transformation of the set of camera responses, with the forward transformation being estimated from a representative (“training”) data set. If the number of coefficients is more than the number of response values, then the latter may need to be increased by imaging the scene under different illuminants or by introducing colored filters one at a time in front of the camera to modify the sensor spectra. An alternative to the

two previously mentioned configurations is the use of a monochrome camera coupled to a monochrome sensor and a set of band-pass filters (Fig. 5).

Applications

Hyperspectral imaging is used in many fields where applications demand high spatial and spectral resolution and need accurately color coding between similar colors or materials. For instance, in agriculture, hyperspectral imaging enables monitoring of plant health, pest control, and evaluation of ripeness. Classical applications can be also found in astronomy where ultraspectral imaging systems allow to inspect planets at distance or to determine a spatially resolved spectral image of stars. In food processing and research, hyperspectral imaging systems are used to identify defects, apply intelligent food classification, and characterize product quality. In remote sensing, spectral systems (when mounted in a drone) are now able to track forest health, water quality, or potential sources of fires. In general, spectral imaging is also becoming more and more popular in museums, geology, chemical imaging, skin care, cosmetics, etc.

Hyperspectral Imaging of Pictorial Artworks

Spectral imaging is a very powerful technique which, when properly applied, can retrieve useful information from art objects in a noninvasive manner. This is especially important when the objects are very old and delicate, such as paintings, ancient documents, old maps, etc. [1, 6, 13]. All these items are subject to the action of degradation agents as well as the intervention of conservation and restoration professionals. The main problem in these spectral applications is that the illumination is no longer so well controlled. Even if standard light sources are used to illuminate the painting, it will not be homogeneously illuminated, presenting highlights and shadowy areas due to the common presence of high reflectivity binders, varnishes, or materials. Moreover, different spatial locations and spectral bands might register huge variations in intensity

H

Hyperspectral Imaging, Fig. 5 Pixelteq Spectrocam VIS-NIR with the 8-slot filter wheel facility and the available set of 16 band-pass filters in the visible and near-infrared spectrum (from <https://pixelteq.com/>)

of the reflected light from the painting. This might exceed the dynamic range of the device, making it necessary to use HDR techniques to be able to recover useful information for each pixel and every spectral band [6, 13].

Unfortunately, hyperspectral scanners only allow one exposure time to be set for each complete capture, which means that in a single scan, all the wavelengths and areas of the scene are captured using the same single exposure time. In these uncontrolled conditions, the high dynamic range and the focusing problem due to chromatic aberrations can be overcome by using multiple captures with different focus positions and exposure times. Figure 6 shows how the use of a low dynamic range hyperspectral cube can affect the color fidelity of the rendered painting in comparison with the use of an HDR cube.

In addition, recent studies have shown how spectral imaging also allows surface geometry recovery of the whole scene. A six-band scanner can be used as a multispectral imaging system in such a way that the surface properties of a

painting, spectral reflectance of each pixel and the shape information of normal surface and height can be estimated [14]. This is of particular interest in painting analysis because experts can have access to the usually complicated shape of surfaces of paintings (i.e., irregular canvas, not uniform painter strokes on the canvas, etc.).

Multispectral Imaging of Natural Scenes

Acquiring outdoor spectral image data is an extra challenge because the radiometric conditions of the image scene are generally not static and the illumination does not have a smooth spectrum. Therefore, additional measures for dealing with these issues are required. Due to the great deal of time needed for hyperspectral imaging techniques, multispectral imaging based on indirect measurements can be an easy alternative. Using a conventional RGB color camera with a limited set of one to three broadband color filters (i.e., number n of bands of 4–6) in combination with a direct-mapping method [11], the spectral reflectances of natural scenes can be recovered with

Hyperspectral Imaging, Fig. 6 Comparison between a color image rendered from a hyperspectral image capture using (left) a low dynamic range LDR cube and (right) a high dynamic HDR cube. Two spectra from different areas

of the image are shown below by comparing the spectra obtained from the hyperspectral imager and conventional spectroradiometer measurements

Hyperspectral Imaging, Fig. 7 Examples of recovery of the spectral power distribution of fluorescent illuminants using a multispectral imaging system (RGB color camera with a broad-band color filter) [15]

good spectral and color quality. Given a set of training spectra $\mathbf{S}$ (i.e., spectral radiances or spectral reflectances at a pixel) and the corresponding set of camera responses $\mathbf{C}$ (as defined by Eq. 1), a recovery transformation matrix $\mathbf{D}$ can be defined by $\mathbf{D} = \mathbf{S}\mathbf{C}^+$, where $\mathbf{C}^+$ is the pseudo-inverse of $\mathbf{C}$. If $\mathbf{C}$ has full rank, then $\mathbf{C}^+ = (\mathbf{C}^t\mathbf{C})^{-1}\mathbf{C}^t$, where $\mathbf{C}^t$ is the transpose of $\mathbf{C}$. An estimate $\mathbf{S}_e$ of a set of test

spectra $\mathbf{S}_p$ may then be obtained from the corresponding set of camera responses $\mathbf{C}_p$ by applying the transformation $\mathbf{D}$, that is, $\mathbf{S}_e = \mathbf{D}\mathbf{C}_p$. Direct-mapping is an easy and a fast procedure to get spectra recovery of a pixel without consuming much time; however, the training step should be carefully taken into account to get accurate results [8, 11, 12].

Multispectral Image Capture of Natural and Artificial Illumination

Although intense research has focused on the analysis of multispectral data to recover spectral reflectance functions of objects, spectral recovery in the context of the spectral power distribution of artificial illumination has received little attention. Natural and artificial scene illuminant recovery can also be addressed by estimating the spectrum distribution of an unknown illuminant using a spectral camera system. Spectral characterization of both daylight and artificial illumination is important in fundamental research and applications, in particular for the analysis and synthesis of scenes. Nevertheless, artificial illuminants, such as fluorescent light, are characterized by complicated spectral power distributions (i.e., containing several pronounced peaks) which so far are difficult to spectrally estimate [15]. An accurate spectral estimation of fluorescent lights can be obtained by using a direct-based spectral imaging setup with a monochrome CCD camera attached to a liquid crystal tunable filter (Fig. 7).

Ibn Rushd (Averroes)

Eric Kirchner

Kirchner Publications, Leiden, The Netherlands

Abu'l-Walid Muhammad bin Ahmad Ibn Rushd (Latinized name: Averroes) was born in Cordoba (Spain, 1126) and died in Marrakech (Morocco, 1198). His works range from philosophy, astronomy, and medicine to religion. He would be the most influential of Aristotle's medieval commentators, writing comments, and corrections on all the

Aristotelian works available to him [1]. Scholars in Christian Europe would refer to him as “the Commentator [of Aristotle].” The revival of Aristotelism in twelfth century Europe was mainly based on Ibn Rushd's commentaries. But in the Islamic world, Ibn Rushd's defense of rationalist philosophy would be less influential than the religious Asharite philosophy that emphasized divine manifestations in nature, as advocated by al-Ghazali.

Ibn Rushd tried to formulate a theory of light and color, as consistent with Aristotle and his followers as possible. Like Ibn Sina had done before, Ibn Rushd provided many arguments why the so-called extramission theories from Ptolemy and Euclid are absurd, and vision cannot be caused by visual rays emerging from the eye. And similar to Ibn Sina, Ibn Rushd explained vision in terms of Forms transmitted from the visible object to the eye, i.e., an intromission theory [2].

Ibn Rushd maintained that colors exist even when they are not perceived, and that light is necessary for colors to be visible [3]. Like Ibn al-Haytham had done before, Ibn Rushd considered light as playing an active role in color vision, thus breaking with the traditional Aristotelian view. But unlike Ibn al-Haytham, Ibn Rushd did agree with Aristotle that also the medium played an active role in color vision. Apparently, Ibn Rushd was not aware of the theory on vision that had been proposed by Ibn al-Haytham, successfully combining the various classical theories into one mathematical–physical intromission theory of light, color and vision.

Ibn Rushd explained the different species of color as consisting of various mixtures of bodies of much or little transparency with bodies of much or little luminosity. Since every material is composed of the four elements, with only water and air being transparent and only fire being luminous, the color of a material can be attributed to the relative amounts of the elements. This explanation was later adopted by Theodoric of Freiberg (p. 172 of Ref. [4]), who explained it in terms of four principles (much or little transparency, much or little luminosity) of colors.

Ibn Rushd did not agree with Ibn Sina's criticism of the Aristotelian ideas on color mixing. In his *Jawāmi' al-āthār al-'ulwiyya* (Short Commentary on the Meteorology: 74, 19–76, 18), Ibn Rushd defended the Aristotelian view by arguing that it referred to color mixing in a qualitative sense, but not in a quantitative sense [5, 6]. For example, Ibn Rushd argued that green is formed by mixing the yellow that exists in light red with the black that is in purple. From a modern point of view, this makes the approach philosophical rather than scientific.

Also in his description of the rainbow, Ibn Rushd closely followed Aristotle: the rainbow forms by reflection of sunlight on individual rain drops that reflect light and transmit color [4].

Ibn Rushd's ideas on color would be influential on later scholars. In his works on colors (*De coloribus*) and on the rainbow (*De iride*), Theodoric of Freiberg (d. 1318) makes clear that his theory on the formation of colors is based on Ibn Rushd's color theory (p. 47 of Ref. [7]; p. 11 of [8]). Theodoric literally quotes the Latin translation of Ibn Rushd's *Tractato de Sensu et Sensato* (p. 35n2 of Ref. [7]) [9]. His description of the colors of the rainbow, and also his four principles by which color is explained were all explicitly taken from Ibn Rushd's work.

Ibn Sahl, Abu Sa'd al-'Ala'

Eric Kirchner¹ and Seyed Hossein Amirshahi²

¹Kirchner Publications, Leiden, The Netherlands

²AUT Textile Department, Amirkabir University of Technology, Tehran Polytechnic, Tehran, Iran

Abu Sa'd al-'Ala' Ibn Sahl lived and worked as a geometer at the Abbasid (circa 940 – 1000) court in Baghdad. He wrote important works on geometric optics, mathematics, and astronomy. Nowhere in his extant works, Ibn Sahl dealt with (or even mentions) vision [1].

While investigating the transparency of the heavenly spheres that occur in Aristotelian cosmology, Ibn Sahl decided to study Ptolemy's classical work *Optics*, written in the second century AD. This made Ibn Sahl to be the first in the Arabic sources to have read and correctly understood Ptolemy's theory of refraction [1]. Ibn Sahl utilized this theory in an entirely original way for

Ibn Sahl, Abu Sa'd al-'Ala', Fig. 1 With the triangles in the top diagram, Ibn Sahl illustrated the law that is currently known as Snell's law. © Iranian National Library, Tehran. Manuscript MS 687

constructing burning instruments such as lenses and glass spheres by means of refraction.

In the year 984, Ibn Sahl wrote the treatise "On Burning Mirrors and Lenses." In this work, he investigated the optimum (nonspherical) shape of lenses and mirrors to focus light at a given distance. Ibn Sahl "appears to be the first in history to engage in research on burning lenses" [2]. He subsequently treated the parabolic mirror, the ellipsoidal mirror, the plano-convex lens, and the biconvex lens. His calculations on geometric aberration predate similar calculations done by Descartes in the 1620s. Ibn Sahl carried out these calculations both for light sources at an (almost) infinite distance such as the sun and for light sources at finite distances [3].

In these calculations, Ibn Sahl needed a law of refraction. Intriguingly, for this he used a law that is geometrically equivalent to Snell's law that would be rediscovered in 1621 by Willebrord Snellius and in 1602 by Thomas Harriot. The sine law of refraction was thus discovered by Ibn Sahl [4, 5].

The illustration shows a page from Ibn Sahl's manuscript. In the top part of the figure, two

overlapping triangles are shown. The hypotenuse of the external triangle represents the direction of incident light, while the hypotenuse of the internal triangle represents the direction of refracted light inside a transparent medium. By demanding that these two direction vectors intersect in one point, constructing the direction of refracted light with this figure is geometrically equivalent to keeping the ratio of sines of incident and refracted angles constant. This is Snell's law of refraction.

Ibn Sahl used this law of refraction several times in the treatise, but without explicitly stating it as a law [4, 5]. Indeed, the concept of natural law did not exist at the time. Ibn Sahl used his law as if it was a mathematical relation that was well known. He repeatedly applied this relation, utilizing the fact that the ratio between the sines of incoming and refracted angles is constant. He made no reference to the fact that this constant depends on material-dependent properties, i.e., what is now known as their refractive index.

Ibn Sahl's treatise was later used by Ibn al-Haytham in his investigations of refraction. Interestingly, Ibn al-Haytham apparently did not

recognize the law of refraction as used by Ibn Sahl. Instead, Ibn al-Haytham started his own experimental investigation into finding a law of refraction.

Illuminance Meter

Bor-Jiunn Wen¹ and Chao-Hua Wen²

¹Department of Mechanical and Mechatronic Engineering, National Taiwan Ocean University, Keelung, Taiwan

²Center for Measurement Standards, Industrial Technology Research Institute, Hsinchu, Taiwan

Synonyms

[Luxmeter](#)

Definition

In photometry, Illuminance Meter is a device that measures the total luminous flux incident on a surface, per unit area. Illuminance is a measure of how much the incident light is spread over a given surface, wavelength-weighted by the luminosity function to correlate with the brightness perception of human eyes.

Introduction

There are many units for defining illuminance. The International System of Units defines using the unit of lux (symbol: lx) or lumens per square meter (cd sr m^{-2}), which is most frequently used. In the centimeter-gram-second system, the unit of

illuminance is the phot, which is equal to 10,000 lx. The foot-candle is a nonmetric unit of illuminance that is also used in photography. Illuminance is sometimes called brightness, but this leads to confusion with other uses of the word, such as brightness perception. Hence, “brightness” should never be used for quantitative description, but rather for describing the visual perceptions of light or color.

The human eye is capable of seeing within a range of more than two trillion-fold. The presence of white objects is somewhat discernible under starlight, at 5×10^{-5} lx, while at the bright end, we can easily read large text at 10^8 lx, or at about 1000 times that of direct sunlight, although this can be very uncomfortable and cause long-lasting after-images.

Application 1

In addition to an illuminance meter, illuminance color spectral meters including spectrometer, spectrophotometer, spectrograph, or spectroscope are also important for measuring properties of light over a specific portion of the electromagnetic spectrum, typically used in spectroscopic analysis to identify materials [1]. The parameter measured is most often the light’s intensity, but could also be, for instance, the polarization state. The independent variable is usually the wavelength of the light or a unit directly proportional to the photon energy, such as wave number or electron volts, which has a reciprocal relationship with wavelength. A spectrometer is used in spectroscopy for producing spectral lines and measuring their wavelengths and intensities. “Spectrometer” is a term applied to instruments that operate over a very wide range of wavelengths, from gamma rays and X-rays into the far infrared. If the instrument is designed to measure the spectrum in absolute units rather than relative units, then it is typically called a spectrophotometer. The majority of spectrophotometers are used in spectral regions near the visible spectrum. A spectrograph is an instrument that separates an incoming wave into a

frequency spectrum. There are several kinds of machines, referred to as spectrographs, depending on the precise nature of the waves. Spectroscopes are often used in astronomy and some branches of chemistry. Early spectroscopes were simply prisms with graduations marking wavelengths of light. Modern spectroscopes generally include a diffraction grating, a movable slit, and some kind of photodetector. It is all automated and controlled by a computer.

Application 2

In general, much of computer vision, image processing, and imaging is predicated on the assumption that there is a single prevailing illuminant lighting a scene. However, often multiple lights are present. Common examples include outdoor scenes with cast and attached shadows, indoor office environments that are typically lit by skylight and artificial illumination, and the spotlighting used in commercial premises and galleries. Relative to these mixed lighting conditions, many imaging algorithms based on the single light assumption can fail. Therefore, Finlayson et al. [2] proposed a method of detecting multiple illuminants in images based on the chromogenic theory. By forcing the lights to be examined pair-wise without insisting on the accuracy of the illuminant estimation, and by processing the results on the basis of region rather than pixels, the research obtained very accurate results over a variety of illuminations. Accordingly, the results are remarkably good, especially considering the simplicity and speed of the method.

Calibration

In the color measurement field, calibration is desired to ensure that the system is closely monitored in well working conditions. The traceability chain of illuminance is presented in Fig. 1 [3]. An illuminance meter calibration set-up is shown in Fig. 2 [3]. First, warm up the multimeters. Check

Illuminance Meter, Fig. 1 Traceability chain of illuminance

Illuminance Meter, Fig. 2 Schematic diagram of illuminance meter calibration

that the power of the device under test (DUT) is sufficient. Check the connections of all the instruments as shown in Fig. 1. They should be well connected, including the polarity of the lamp. Second, align the lamp filament to the axis of the light source and fix the position of the DUT.

Third, turn on the power supply after the multi-meters have already warmed up. Ramp up the lamp current to operation value. Execute calibration after the standard lamp has stabilized. Fourth, read the output current of the $V(\lambda)$ [4] (the spectral luminous efficiency function for photopic vision)

detector, and calculate the illuminance of the position of the $V(\lambda)$ detector. Finally, replace the $V(\lambda)$ detector with the test sample at the same position, and record the test reading on the recording card.

Definition

Image quality is commonly characterized as the perceived image degradation with respect to an ideal undistorted image.

Overview

For many applications in research and industry, there is a constant need for quality assessment of images (e.g., computer graphics, image compression, camera manufactures, medical imaging).

Image quality cannot be formalized in general since it plays a different role depending on the application. For example, in *lossy compression* and *streaming*, the perceived quality-to-bit rate ratio with respect to a reference image needs to be maximized, whereas in computer vision, forensic, and medicine, the image quality is driven by *task performance* (i.e., how much semantic information is conveyed in the image). In photo-realistic image synthesis (e.g., 3D computer games, movies), image quality can be regarded as a measure of realism (photography versus rendered image). Moreover, in art and in particular in photography, image quality is strongly influenced by content and salience (see ► [“Image Fidelity”](#)).

Apart from photographic lens distortions, image quality is largely affected by common factors such as noise, blurring, ringing (sharpening), aliasing, dynamic range compression, color quantization, image resolution, and application-specific artifacts (e.g., JPEG compression, rendering artifacts).

Image Quality Assessment

Image quality assessment can be divided into *subjective quality assessment* and *objective quality assessment*.

In subjective quality assessment, human observers independently and subjectively quantify the quality of an image by assigning it a single number that represents the quality score. The average is referred to as the *mean opinion score* (MOS). Objective quality assessment refers to the task of automatically evaluating the quality of images in a way human observers would do.

With today's new technologies, the spectrum of image quality degradations has widened including distortions coming from 3D stereoscopy, ► [high-dynamic-range \(HDR\) imaging](#), 3D image synthesis, and light-field imaging.

Image Quality Metrics

Automatic image quality metrics (IQM) have been developed for the task of objective image quality assessment. Although primarily designed for analyzing still image quality, IQMs have also been exploited for the task of video quality control. However, the human perception of video quality requires proper spatiotemporal modeling of the human visual system (HVS) including also the perception of temporal artifacts like flickering, which is covered by special *video quality metrics*. IQMs can be classified as *full-reference*, *reduced-reference*, and *no-reference* image quality metrics (the latter often referred to as *blind IQM*).

Full-Reference Quality Metrics

Full-reference image quality metrics aim at measuring the strength of general image distortions given two corresponding images, a distorted and a reference (undistorted) one. The given reference image simplifies the detection of universal distortions and their spatial localization in the image but, on the other hand, requires a relatively precise alignment of the two images.

When predicting a single image quality score similar to the subjective MOS, a two-stage approach is pursued. First, a local distortions measure is computed to obtain a quality map. Second,

a spatial pooling algorithm is employed to integrate the local distortions into a single number. Most IQM ignore the *chroma* component and focus only on *luminance* for which the human visual system is most sensitive to.

Full-reference quality metrics can be further divided into *physical IQMs*, *perceptual IQMs*, and *structural and information-theoretic IQMs*.

Physical IQMs have a clear physical meaning, are fast to compute, and are easy to differentiate making them preferred candidates for mathematical optimization techniques (energy minimization). Common physical IQMs are *mean-square error* (MSE), *peak signal-to-noise ratio* (PSNR), *mean absolute error*, and its generalization the *Minkowski error metric* using the l_p norm:

$$E_M = \left(\sum_{i=1}^N |x_i - y_i|^p \right)^{1/p}$$

where x_i, y_i are the values of the i th pixel in the distorted and reference image respectively and p is a positive real number.

Physical IQMs consider an image as a collection of N independent pixels x_i thereby ignoring any correlation among them. As shown in Fig. 1, the human-perceived error with respect to a reference image varies locally depending on the brightness, frequency, and correlation of the reference image content and the error signal.

Therefore, *perceptual image quality metrics* have been developed in order to better predict the perceived image quality (image similarity), which they achieve by simulating the early pathways of the human visual system (HVS) modeling effects such as *light adaptation*, *luminance masking* (Weber's law), *contrast sensitivity function* (CSF), and *contrast masking* (also known as *visual masking*). For this reason they are also referred to as *bottom-up* quality measures. Various perceptual models for image quality were proposed: the visual difference predictor (VDP) [5], the Lubin model [3], HDR-VDP [2], Watson's DCT model [4], JPEG 2000 [6], etc. Many of these models are relatively complex and computationally intensive but predict the human-perceived distortions reliably near the visibility

Image Quality, Fig. 1 Nonlinearity of the perception of image quality: images (a) and (b) have exactly the same root-mean-square error (RMSE) with respect to the original images (c) and (d), respectively. However, the distortions in image (b) are visually disturbing while they are almost invisible in image (a). This perceptual effect is referred to as *masking*. Note that the distortions in image (b) are more

salient in dark regions and regions with frequency content (e.g., sky) different from the error signal (g). Images (e) and (d) exhibit approximately the same perceived image quality as predicted by the structural similarity (SSIM) index metric [7]. Please note that the distortions perceived in the images depend on the display size of the images

threshold (super-threshold). However, because they are mostly tuned to experimentally acquired visibility thresholds measured on simple stimuli, the prediction of strongly visible distortions (supra-threshold) is questionable and remains still an open research field.

To overcome the complexity of HVS-based metrics, structure-based metrics (e.g., SSIM [7])

have been derived that do not explicitly model the HVS but merely compute a relatively simple statistical measure of image similarity based on local pixel-value correlation and contrast.

Information-theoretic image quality metrics predict the perceived image quality using a statistical approach. They estimate how much information is shared between the reference and distorted

image assuming the distorted image is transmitted over a noisy communication channel. Exploiting entropy-based methods known from signal coding and compression, the perceived quality of an image is computed from the *mutual information* of the reference and distorted image. A known information-theoretic quality metric is, for example, the *visual information fidelity* (VIF) index [8].

No-Reference Image Quality Metrics

No-reference (blind) image quality metrics pursue a top-down approach for predicting the quality of a single image. Thereby, the HVS is treated as a black box, and the quality of an image is predicted utilizing classification or regression techniques that operate on distortion-specific image features (e.g., gradient histograms, wavelet coefficients). No-reference IQMs require careful modeling of the image features and need many image examples for training a supervised learning algorithm (e.g., a support vector machine) [9]. Therefore, no-reference IQMs do not generalize well and are typically tuned to detect only one or a few specific image distortions (e.g., JPEG blockiness, noise, blur) where the success of the prediction primarily depends on the complexity of the type of distortion. Typical no-reference IQMs are based on features computed from Natural Image Statistics.

Reduced-Reference Image Quality Metrics

In a streaming scenario, full-reference IQMs cannot directly be applied for predicting the image quality on the client side since only the server knows the reference and the distorted image. On the other hand, no-reference IQMs are less reliable and in general also more expensive to compute than full-reference IQM. Therefore, a new paradigm for quality control has emerged, which is called reduced-reference IQM. Reduced-reference IQMs sparsely encode auxiliary information about the reference image that is streamed together with the lossily encoded image and enables the client to faithfully compute a quality score for the decoded image. The more data about the reference image is streamed, the better the

client can predict the image quality degradation. Thus, reduced-reference IQMs trade quality information for bit rate and can be regarded as a compromise between full-reference IQM and no-reference IQM.

Impressionism

Georges Roque
Centre National de la Recherche Scientifique
(CNRS), Paris, France

Definition

Impressionism is considered as the first vanguard movement of Occidental art history; it opens modernity in art. Its starting point is a group of artists who had in common a rejection of academic art. They organized eight collective exhibitions between 1874 and 1886. Most of the artists only took part in some of these exhibitions, like Cézanne. The painters considered as more “typically” impressionist are above all Claude Monet, Pierre-Auguste Renoir, and Camille Pissarro.

Overview

The term “impressionist” was coined by a critic as a nickname in order to criticize the movement, as he was struck by a painting presented by Monet in the first 1874 collective exhibition and entitled *Impression, soleil levant* (*Impression, Sunrise*). The novelty of Impressionism is twofold. First, it has to do with the subject matter, often taken from everyday life (train stations, boulevards, scenes of leisure, etc.), corresponding so to Baudelaire’s conception of modernity. And second, it is technical: the way of rendering light, color, atmosphere, the nature of the brushstrokes, the innovative composition, and the impression of unfinished and incompleteness are among the main features of Impressionism.

Theory and Practice

According to the standard account of Impressionism (largely widespread by one of his best

specialists, John Rewald), the Impressionists did not need any theory, since they trusted their eye. For sure, some of the statements made by Monet and Renoir seem to reinforce such a conception. However, the issue of the relationship between Impressionism and color science is more complex. The first part of this paper is devoted to general features of Impressionism regarding color and the second one to the conception of color that can be found in Monet, Renoir, and Pissarro.

First of all, it must be noted that, unlike Neo-impressionist painters, the Impressionists did not write “theoretical” essays, so that they have not conveyed a general idea of their principles. Furthermore, what they had in common was a rejection of academic art more than a clear doctrine. For this reason, the practice of the group members differs a lot from each other and depends more on personal skills than on shared beliefs, even though they had in common some general aims, like the ideal of modernity or the fact of preferring the rendering of ever-changing moments and atmospheres instead of permanent features. Yet, this does not mean that they had an “empirical” practice. Even though Monet liked to say, “I have already had a horror of theories” [1, p. 586], it should be recalled that such a statement does not mean that Monet rejected all theories but only dogmatic submission of practice to a theory prior to it, as did Bonnard and Matisse, too.

An often-quoted passage is usually given as an example of Monet’s “empirical” practice: “When you go out to paint, try to forget what objects you have before you, a tree, a house, a field or whatever. Merely think here is a little square of blue, here a oblong of pink, here a streak of yellow, and paint it just as it looks to you, the exact color and shape, until it gives your own naïve impression of the scene before you” [2, p. 35]. This passage recalls Ruskin’s famous conception of an “innocent eye”: “The whole technical power of painting depends on our recovery of what may be called the *innocence of the eye*: that is to say, of a sort of childish perception of these flat stains of colour, merely as such, without consciousness of what they signify” [3, p. 27].

Georges Roque has retired.

Monet – who praised a lot Ruskin's *Elements of Drawing* – coincided with Ruskin in the attempt to retrieving the “innocent” eye, that is to say, trying to paint things not as they are known but as they are seen. The problem, however, is that there is no “purely” visual perception: the so-called innocent eye also depends on an implicit or explicit knowledge about the perceptual ► **appearance** of what is seen, knowledge that, in turn, depends on cultural background. Not surprisingly, the fact of seeing out in the world not “objects” but stains of colors corresponds to what scientists said at the time: perception of objects is the result of a psychophysiological process in the brain [4, p. 427]. Similar ideas were already present in the field of literature and art criticism. In his obituary of Delacroix, Baudelaire wrote that there are neither lines nor colors in nature, for they are created by man [5, p. 752]. It must be added that the vocabulary of artists is also borrowed from science. From this point of view, “impression” corresponds to the empiricist view according to which in visual perception it is the first impression not yet reworked by thought. The new meaning given by Helmholtz to the concepts of “impression” and “sensation” had been popularized in France through Taine's *De l'Intelligence* (1870); artists, however, often used them as if they were equivalent.

Optical Mixture

It is generally assumed that the Impressionists achieved the particular and luminous effect of their paintings through a particular technique, known as “division of the tone” and consisting in breaking down colors into their constituents. Duranty, one of the first critics of the movement, explained indeed, “Proceeding from intuition to intuition, they [the Impressionists] have little by little succeeded in breaking down sunlight into its rays, its elements and to reconstitute its unity by means of the general harmony of the iridescent color which they spread on their canvases [...] The most learned physicist could find nothing to criticize in their analyses of light...” [2, p. 4].

It could be thought that critics were just trying to find a way to give a scientific legitimacy to a young movement highly criticized, arguing that their way of painting was “scientific,” which in fact is not true [6]. However, besides similar comments made by other critics, there is a more precise text based on conversations with Pissarro and that the painter never disowned:

About that time [1870–1871], M. Pissarro, after a holiday at Piette in Britain, went to London with M. Claude Monet. During their 10 months stay in this city, they sent canvases to the National Academy, which then condemned the painters' audacity. Nevertheless, on British soil, their eyes had been educated by Turner, who had for a long time restricted himself solely to the colors of the prism. In their study of his work, they found confirmation of theories already discussed in private and realized in individual essays that had not yet been publicly shown: *the law of complementary colors and its natural end, the division of the tone*.

This stay in England hastened the Impressionist's evolution. Back in Paris, Pissarro and Monet made themselves the exegetes of the new technique. Quickly, their friends, prepared by previous attempts, recognized the superiority of the retinal color mixture over the obviously darker mixture that occurs on the palette. The optical reconstitution of the complementary colors divided on the canvas finally gave them those blond lights so patiently sought.

Impressionism, stemming from precise theories, soon emerged with the brilliance of its luminous and vibrating harmony [7]

This text shows at least that Pissarro and Monet attempted something considerably beyond “empirical” practice of painting: they needed theoretical explanations grounded on the scientific knowledge available in their time in order to confirm their practice. Indeed, the “law of complementary colors” refers to the theory of the French chemist Michel-Eugène Chevreul, who was very influential at the time and is directly or indirectly the main source of the Impressionist color theory [8]. According to Charles Blanc, a very important art historian (he was also director of the Paris École des Beaux-Arts), whose book *Grammar of*

Painting and Engraving was avidly read by the artists at the time, “it is the mutual exaltation of juxtaposed complementary colors that Mr. Chevreul called ‘the law of simultaneous contrast of colors’” [9, p. 562]. If two ► **complementary colors** are juxtaposed, indeed, they enhance each other, and Impressionist painters were eager to use bright colors. For this reason, they took seriously the harmony of complementary colors. They also thought that they would obtain a more luminous result when juxtaposing dots of colors (and particularly dots of complementary colors) that were supposed to fuse in the eye; for this reason, the “division” of the tone is directly related to the law of complementary contrast. What has been called “indigomania,” due to a pervasive use of violet and blue in Impressionist canvases, has a lot to do with this issue [8, pp. 34–36]. Georges Guérout (one of the translators of Helmholtz into French) gave indeed an explanation for the use of violet and blue, in particular for shadows: “The *plein air* school is right to put blue or violet in the shadows. For yellow, whose complement is violet, dominates much in the sun, and, by contrast, violet dominates in the shadow” [10, p. 176].

Artificial Pigments

Besides harmony of ► **complementary colors**, another general feature of Impressionism is the use of artificial pigments that had been recently introduced in the color market [11, 12]. Furthermore, they liked to use them pure, as they come from the tube, that is, without mixing them. Such a use has been deeply criticized at the time, as pure hues were not considered as “true” artistic colors. According to this dated conception, colors, in order to be accepted as artistic, have to be prepared and mixed. The reason for the Impressionist practice regarding pigments is related to their modernism: painters were proud to use newly created synthetic pigments instead of the old ones; furthermore, using them pure was also another way of being modern, as it entailed a strong critique of the traditional view according to which painters had to prepare their own colors.

Renoir, Monet, and Pissarro

After this general overview, a look at some painters in particular could confirm, despite what is generally assumed, that they were interested in color theory and applied it to their works. From this point of view, artists’ statements do not have to be taken literally. Renoir once explained that he painted “like a child,” and he added, “I don’t have neither rules nor methods” [13, p. 13]. However, a closer look at his writing shows that he was aware of the fact that the brightness of a hue depends on the other colors contiguous to it. When Julie Manet asked him advices as how to improve a still life on a white tablecloth, Renoir explained to her that “one has to give white its intensity thanks to the value of what surrounds it, and not by adding more white to it” [13, p. 223]. Now, this is exactly one of the six advices Chevreul gave painters: white placed beside a color heightens its tone [14, § 336].

Exactly the same warning can be made about Monet’s statements. And in his case, too, relevant information confirms his interest for color theory. In an interview given in 1888 to an English newspaper, he explained, “Color owes its brightness to force of contrast rather than to its inherent qualities [...] ► **primary colors** look brightest when they are brought into contrast with their complementaries” [11, p. 88]. This statement explains his well-known taste for the field of poppies he painted very often, as they gave him an excellent opportunity to juxtapose green surfaces with patches of red, enhancing so the two ► **complementary colors**. Another source of information is the visit the painter Louis Anquetin made to Monet in order to inquire into his conception of color. According to Émile Bernard’s account of this visit, Anquetin was disappointed, realizing that Monet “only knew a very little part of what he was coming to ask him, contenting himself with the theory of the complementary colors, applied with the palette of the seven prismatic colors” [15, p. 112]. This information confirms that Monet used the harmony of complementary colors. It should also be noted that Monet’s well-known interest for light reflections in water has also to do with scientific theories [16].

Now, what about Pissarro? According to Geffroy, he “was always passionately and learnedly interested in the theories of lights and colors, fervent in the search for processes, always ready for research and realization” [17, p. 263]. Not surprisingly, his contribution to color is also remarkable, in particular concerning frames. As a critic recalled, “At the 1877 Exhibition, M. Pissarro, applying in its rigorous logic the law of the complementary colors, set his canvases into white frames that, without influencing the colors, left the tones with their exact values” [7]. Indeed, Chevreul had actually drawn attention to the influence of the colors of the frame on the colors of the framed work and had argued against the use of gilded frames [14, §565]. Since Chevreul was probably the only scientist to have paid attention to this problem at the time, Pissarro could not have learned it from any other source. Pissarro liked the idea and used white frames for his paintings, after convincing his dealer to do so. In 1881, for the Sixth Impressionist Exhibition, Pissarro innovated again: he tinted the stretchers with the complementaries of the color dominating in the painting, which was another original way of enhancing the colors of his paintings.

To conclude, even though in some statements Impressionist painters said they had a purely empirical conception of color and were not interested in theory, there is enough evidence showing that they were using recipes allowing them to enhance their colors. For this aim, Chevreul’s law of simultaneous contrast, as understood by Blanc and others, provided excellent tools and advices. Closer technical analysis of Impressionist paintings confirms their frequent use of juxtaposed ► [complementary colors](#) [11, 12].

Inappropriate Use of Color

► Color Pollution

Incandescence

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Definition

Emission of optical radiation by the process of thermal radiation.

Thermal radiation is electromagnetic radiation originating in the thermal motions of particles of matter (atoms, molecules, ions, etc.). All matter above the temperature of absolute zero emits thermal radiation. Objects around room temperature emit mainly infrared radiation. Objects at temperatures higher than some 800 K also emit electromagnetic radiation in the visible area.

Thermal Light Radiators

- The Sun that generates light by its hot plasma with a temperature of around 6,000 K
- Glowing coal and red hot horseshoe with a temperature of around 1,000
- Torches, oil lamps, candles, and gas lamps with temperatures of around 2,000
- Carbon-arc lamps with temperatures of up to 5,000 K
- Old-fashioned chemical flash bulbs with temperatures of around 4,000 K
- Incandescent lamps with temperatures of 2,700 K
- Halogen incandescent lamps with temperatures of 2,900–3,200 K
- Black body radiator

Black Body Radiator

A black body radiator is an ideal thermal radiator that completely absorbs all incident radiation, whatever the wavelength, the direction of incidence, or the polarization. It is also referred to as Planckian radiator. The research on and description of the behavior of thermal radiators is based on this ideal thermal radiator. Black body radiation is also the basis for the correlated color temperature of gas discharge and solid-state light sources.

The thermal radiation of a black body radiator depends solely on the temperature of the material (T) and is completely described by three laws: the law of Planck, the law of Stefan-Boltzmann, and the displacement law of Wien. The law of Planck defines the continuous spectrum of the black body radiator. The law of Stefan-Boltzmann states that the total radiant flux increases proportionally to T^4 . Wien's displacement law defines how the peak of the spectrum shifts to shorter wavelengths with an increase of T (i.e., from the infrared region of the spectrum via the red part of the visible spectrum to the blue part of the visible spectrum).

Incandescent material used for actual lamps such as tungsten filaments of incandescent and halogen lamps behaves similarly to the black body radiator but with some important differences.

Characteristics of Commercial Incandescent Lamps

The efficacy of incandescent lamps is with some 5–30 lm/W (dependent on type and wattage) low compared to that of gas discharge lamps and solid-state LED light sources with values between 50 and 200 lm/W. The average lifetime with values between 1,000 and 3,000 h is short relative to the economic lifetime of gas discharge lamps and LED lamps with values varying, with type, from some 10,000–10,000 h. The temperature of the incandescent filament is limited to some 3,200 K because at higher temperatures the material will evaporate quickly or even start to burn. The consequence is that the continuous spectrum of both the incandescent and halogen lamps has its

peak in the red part of the spectrum. The peak with the halogen type is slightly more to shorter wavelengths. The color of the light is warm white (color temperature between 2,700 and 3,200 K). Since the spectrum is continuous, the color rendering index is 100.

Incandescent Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Incandescent bulb](#); [Tungsten filament lamp](#)

Definition

A lamp that produces light as a result of electrical current through a tungsten wire contained in a transparent bulb, which heats the metal to incandescence.

Incandescent Lamps

There exists a wide variety of incandescent lamps, ranging from the most common types (usually referred to as general lighting service, GLS,

lamps) to reflector lamps, colored lamps, and halogen incandescent lamps [1, 2]. Given the special operating principle and construction of halogen incandescent lamps, these will be dealt with separately under “halogen, halogen lamp.” The most important application area of normal incandescent lamps is home lighting. Because of the low efficacy and short lifetime of incandescent lamps, the more efficient and longer-life gas discharge and solid-state lamp alternatives have become increasingly more important for home lighting. For reasons of sustainability, governments in some parts of the world have taken the decision (e.g., Australia and the European Union), or are considering making the decision, to ban GLS incandescent lamps.

Working Principle

The operating principle of the incandescent lamp is simple. An electric current is passed through a thin wire of comparatively high resistance so as to heat this to incandescence. The wire is usually heated to a temperature of between 2700 and 2800 K, at which temperature it emits warm-white light. The wire is placed inside a glass bulb, which is either at a vacuum or contains an inert gas.

Materials and Construction

The main parts of an incandescent lamp are (Fig. 1):

- Glass bulb
- Filament
- Filament support consisting of a glass stem, lead-in wires (also serving as a fuse), and support wires
- Bulb fill gas
- Lamp cap

Filament

With very few exceptions, filaments for incandescent lamps are made of tungsten, a metal that has the advantage of a high melting point combined with a relatively low vapor pressure, even at very high temperatures. This low vapor pressure means

Incandescent Lamp,

Fig. 1 The main parts of an incandescent lamp [3]

a low evaporation rate of the tungsten material and thus a relatively long life of the coil. The tungsten wire is generally wound into a single or double coil for reasons of compactness and heat conservation and concentration around the coil. The double coil (Figs. 2 and 3), which conserves and concentrates the heat better than does a single coil, was patented in 1917. It was the last fundamental improvement of incandescent lamps as far as the operating principle is concerned.

Bulb

The bulbs of GLS lamps are made of soda-lime glass, the most common and cheapest type of glass available. For lamps that must withstand high temperatures or temperature chocks, more resistant glasses are used. The bulb of an incandescent lamp can be of different sizes and may take different shapes, depending on the application. Also depending on the application, the bulb may undergo various treatments. The most commonly employed treatments are:

- **Frosting:** This is done by etching the inside of the bulb. The etching of the surface results in a satin finish and moderate diffusion of the light with hardly any reduction in transmittance.

Incandescent Lamp, Fig. 2 Patent of 1917 of the double-coiled tungsten wire

Incandescent Lamp, Fig. 3 Winding of the tungsten wire into a double coil around a core, which is removed later on in the manufacturing process [3]

- **Opalizing:** This is achieved by coating the inside of the bulb with a special powder. It provides better diffusion of the light at the cost of slightly larger light absorption.
- **Mirror coating:** Reflector lamps receive an internal mirror coating. Silver mirrors are produced by evaporation of aluminum under vacuum.

Fill Gas

Two types of incandescent lamp are available on the market; vacuum lamps and those with a fill gas. The vast majority of incandescent lamps contain a fill gas, the primary purpose of which is to reduce the evaporation rate of the filament and thus increase the lamp life. The fill gas is a mixture of argon and nitrogen. In incandescent car lamps, krypton is usually employed (it is more expensive, but results in a higher luminous efficacy).

Even small quantities of oxygen or water vapor could shorten the lifetime of the tungsten wire through corrosion. To remove even the slightest traces of these, a so-called getter is added. The getter absorbs oxygen and water.

Lamp Cap

The lamp cap connects the lamp to the power supply socket. There are two different standardized cap types: the screw cap (also called the Edison cap) and the bayonet cap. Both are employed in various sizes:

- Edison screw type: IEC designation – E10, E14, E27, E40. In the USA, names rather than IEC designations are used: Candelabra (E12), Intermediate (E17), Medium (E26), and Mogul (E39).
- Bayonet type: IEC designation B15, B22.

The number indicates the diameter of the lamp cap in millimeters.

Properties

Energy Balance

Figure 4 shows the energy balance of a 100 W GLS lamp. It shows that only approximately 8% of the input power is emitted in the form of visible radiation. The rest is lost as heat (by conduction, convection, and infrared radiation).

Incandescent Lamp, Fig. 4 Energy balance of a 100 W GLS lamp [3]

Luminous Efficacy

The luminous efficacy of a standard GLS lamp varies, depending on its wattage, between 8 and 15 lm/W. For a standard 75 W lamp, the efficacy is around 12 lm/W. The lower the wattage, the lower the efficacy.

Compared with gas discharge and solid-state light sources, the efficacy of incandescent lamps is very low indeed. For reasons of sustainability, governments in some parts of the world (e.g., the European Union) have taken the decision, or are considering making the decision, to ban GLS incandescent lamps.

Lumen-Package Range

Common types of GLS lamps are available in the range from some 100 to 1500 lumen (corresponding wattage range approx. 15–200 W). There are, of course, many special lamps with both lower and higher lumen packages: think, for example, of bicycle and torch lamps on the one hand and light-house lamps on the other.

Color Characteristics

Incandescent lamps have a continuous spectrum radiating more energy at longer wavelengths (red) than at shorter wavelengths (blue) (Fig. 5).

Their color rendering index is 100, and standard GLS lamps have a color temperature of between 2700 and 2800 K (warm-white light).

Colored opal lamps for party or festive lighting are available, as are lamps producing a special tint of “white” light (e.g., flame, terracotta, beige).

Lamp Life

Lamp manufacturers can, in principle, balance the life of an incandescent lamp against its luminous efficacy: higher lifetime, lower efficacy. However, by international agreement, the lamp industry has standardized the average rated life of standard GLS lamp at 1000 h (750 h in the USA). Nevertheless, for special applications, lamps are available where the balance between lifetime and efficacy is different. Examples are photo and film-studio lamps and torch bulbs on the one hand with their shorter life but higher efficacy (and higher color temperature) and beacon lamps on the other with their longer life but lower efficacy.

Lamp-Lumen Depreciation

An important reason why the light output of an incandescent lamp decreases with time is that tungsten evaporates from the filament and settles on the bulb wall, blackening it. At the end of the

Incandescent Lamp, Fig. 5 Relative spectral energy distribution of an incandescent lamp [3]

Incandescent Lamp, Fig. 6 A thin spot in the filament eventually resulting in breakage of the filament [3]

rated average life (1000 h), the lumen depreciation can amount to as much as 15–25%.

Run-Up and Re-Ignition

Incandescent lamps give their full light output immediately after being switched on, and after being switched off, they re-ignite again immediately.

Switching

Frequent switching usually is not detrimental to lamp life, but when the filament has become

critically thin through age, the mechanical strain caused by the rapid temperature change as a result of switching will be sufficient to cause its breakdown (Fig. 6). This is the reason why incandescent lamps approaching the end of their life usually fail the moment they are switched on or off.

Dimming

Regular incandescent lamps can be dimmed without restriction. Dimming by reducing the supply voltage to the lamp with an adjustable resistance

Incandescent Lamp,

Fig. 7 Diagram indicating the effects of mains voltage variation on lifetime (L), luminous flux (ϕ), and dissipated power (P)

Incandescent Lamp, Fig. 8 Examples of general lighting service (GLS) incandescent lamp types

in series with the lamp is technically easy but does not result in energy saving. A relatively expensive adjustable transformer (potentiometer) results in energy saving, but not very much. Today the usual method to dim incandescent lamps is by thyristor dimmers that cut part of the AC current during each of the 50 (Europe) or 60 (USA) cycles.

During the time that the current is cut, no power is dissipated, so that indeed energy is saved. These systems are called phase-cutting systems. They are small enough to fit into a wall switch box or cord switch. A dimmed incandescent lamp will have a lower filament temperature, which results in longer life and lower color temperature (warm-

Incandescent Lamp, Fig. 9 Examples of refractor/reflector incandescent lamps

colored light). The lamp efficacy while dimming decreases, which means that the percentage of power saved is less than the percentage reduction in light output.

Mains Voltage Variations

An overvoltage of even a few percent results in a drastically reduced lamp life. For example, a permanent overvoltage of 5% reduces lamp life by 50% (Fig. 7).

Product Range

The product range of incandescent lamps comprises not only general lighting service lamps (in clear, frosted, opal, and colored versions) but also reflector lamps, tubular lamps, decorative lamps, beacon lamps, vehicle lamps (bicycles, cars, trains), signal lamps, and studio and theater lamps. Figures 8 and 9 show some examples of these lamps. All these lamps have blown-glass bulbs (blown from a single “blob” of glass), with the exception of the pressed-glass reflector lamp (PAR). The latter is molded in two pieces, which are sealed together – they are also sometimes called sealed-beam lamps. One advantage of this construction is that the mirror in the rear and the refractor on the front can be accurately shaped to increase the beam quality and efficiency. Another advantage is its high mechanical and thermal

strength, allowing the lamp to be used outdoors without a protecting luminaire.

Induction Lamp

Wout van Bommel
van Bommel Lighting Consultant,
Nuenen, The Netherlands

Synonyms

[Electrodeless low-pressure mercury lamps](#)

Definition

Lamps that produce light as a result of an electrical discharge, generated by an induction coil, in a

low-pressure mercury vapor that is contained in a transparent tube or vessel whose inside is coated with a fluorescent powder that converts the ultra-violet part of the emitted radiation from the discharge in visible light.

Induction Lamps

Induction lamps, like fluorescent lamps, belong to the family of low-pressure mercury gas discharge lamps. Unlike other discharge lamps, they have no electrodes, which is why they are also called “electrodeless lamps” [1, 2]. The consequence of having no electrodes is a very long economic life of around 60,000–75,000 h. This long life is also the main feature of induction lamps. They find their application in situations where lamp replacement is near impossible or very expensive.

Working Principle

In an induction lamp, the free-running electrons needed for the gas discharge are obtained by winding an induction coil around a ferrite core placed in or around a discharge vessel (Fig. 1). The induction coil is connected to a high-frequency power source and acts as a primary winding in a transformer. In a transformer, an alternating current in a primary winding around

Induction Lamp, Fig. 1 The principal parts of an induction lamp. Left, induction coil inside the discharge vessel; right, induction coils around the outer part of discharge tube

Induction Lamp,

Fig. 2 Principle of an induction lamp [3]

an iron core creates an alternating magnetic field that in turn initiates an alternating current in a secondary coil wound around the primary coil. In the discharge vessel or tube, the mercury gas surrounding the ferrite core acts as the secondary coil (since mercury is a metal). The secondary current initiated in the mercury consists of free-running electrons around the ferrite core (Fig. 2). As in a normal fluorescent gas discharge, these free-running electrons ionize and excite other mercury atoms, which results in the emission of the same radiation as in a tubular fluorescent lamp. Since the vessel's interior is coated with the same fluorescent powder as in regular fluorescent lamps, the same type of light is obtained. The high frequency of 2.65 MHz is generated by an electronic circuit.

Materials and Construction

The discharge vessel or tube is made of the same type of glass as regular fluorescent tubes and has, in the case of the internal coil, a cylindrical glass cavity in which the ferrite core with coil (also called "antenna") is positioned (Fig. 3). Special precautions are taken in the design of the lamp to limit excessive heat buildup around the antenna. The high-frequency power generator is connected to the antenna with a coax cable. The cable forms

Induction Lamp, Fig. 3 Photograph of induction lamp vessel and antenna. This lamp is only partly covered with fluorescent powder in order to show the cylindrical cavity in which the coil is positioned [3]

part of the electronic circuit and is, therefore, an integral part of the system (Fig. 4). The version with the coil with iron core around the outside of the discharge tube has a different, planar shape than the pear-shaped version.

Induction Lamp, Fig. 4 Pear-shaped induction lamp with an internal coil (left) and a plane-shaped lamp with external coils

Properties

Energy Balance

Around 17% of the input power of an induction lamp is radiated as visible light. The remaining part is lost as heat in the power generator, in the antenna, and in the discharge.

System Luminous Efficacy

The luminous efficacy of induction lamps is smaller than that of regular fluorescent lamps. It varies, depending on the wattage, between roughly 65 and 75 lm/W.

Lumen-Package Range

Induction lamps are available in a lumen-package range from some 3500 to 12,000 lm (corresponding wattage range 55–165 W).

Color Characteristics

The fluorescent coating is of the same composition as that in regular fluorescent tubes, so the color characteristics are also the same. See chapter ► [“Tubular and Compact Fluorescent Lamp.”](#)

Lamp Life

The lamp life of most induction lamps is extremely long. Based on a mortality rate of 20%, induction lamps have a lifetime of between

60,000 and 75,000 h. This is almost 7 years of continuous operation, day and night.

Lamp Price

Induction lamps are expensive. The high lamp price has to be balanced against the extremely long lifetime of these lamps. This means that where lamp replacement is difficult, very expensive, or even impossible, the balance will certainly be in favor of the longer life of these lamps.

Lamp-Lumen Depreciation

Lumen depreciation in induction lamps is determined by a decrease in the activity of the fluorescent powder. At 60,000 h the depreciation is around 25%, which is why this lifetime figure is usually quoted. The actual life of induction lamps is usually much longer.

Run-Up and Reignition

A high-voltage ignition pulse produced by the HF generator ignites the lamp within 5 s, after which it emits its full light output within 1 min. Thanks to the high-voltage ignition pulse, hot reignition of the lamp is no problem.

Dimming

Most standard versions of induction lamps are not dimmable. However, some special versions, which are dimmable to 50%, are available.

Ambient-Temperature Sensitivity

Amalgam is used instead of pure mercury to keep the sensitivity to ambient temperatures within practical limits. Lamp position sometimes plays a role in this as well. It is therefore important to follow the recommendations from the lamp manufacturer with respect to the luminaire design.

Product Range

As has been shown, induction lamps are available in versions with an internal and external antenna. The corresponding shapes are pear and plane-shaped. They are generally available in color-rendering types 800 and 900, with color temperatures of 3000 and 4000 K.

Definition

A response to color in infancy that indicates that infants can divide the continuum of color into discrete groups.

Key Principles and Concepts

Although humans can discriminate millions of colors, language typically refers to color using a limited number of discrete categories (e.g., *red*, *green*, *blue*). Color categories are not only present in language (color terms), they are also present in “thought.” For example, at least under some circumstances, adults’ perceptual or cognitive judgments of color (e.g., color memory, search, or similarity judgments) are affected by whether colors come from the same or different linguistic color categories [see Hanley]. There has been considerable debate on the origin of color categories and on the extent to which color categories are arbitrarily constructed through language (see ref. [1] for review). To establish whether there is a nonlinguistic route to color categorization, prelinguistic infants’ response to color has been investigated. This has provided converging evidence that infants’ perceptual or cognitive judgments of color can also be affected by whether colors come from the same or different adult color categories. This suggests that color categories are present even in infancy and that even infants, on some level, can parse the continuum of color into discrete groups.

Methods and Examples

Investigations of adults’ categorical response to color have used a range of experimental tasks that provide behavioral or electrophysiological measures of color memory, color search, or chromatic change detection. In these studies, chromatic differences for same- and different-category color pairs are equated, and an influence of the categorical relationship of colors on task performance is assessed. An equivalent approach has been taken to investigate infant color categories. Many of the

Infant Color Categories

Anna Franklin

Psychology, University of Surrey, Surrey, UK

[Prelinguistic color categorization/categorical perception](#)

studies of infant color categories have used the well-established method of *habituation* to assess the influence of categories on infants' response to chromatic novelty. This method involves the repeated presentation of a stimulus (or set of stimuli) until infants' looking time at the stimulus declines (habituation). Then, during a test phase, novel and original stimuli are presented and looking time is recorded. Greater looking to the novel stimulus relative to the original stimulus during the test phase (novelty preference) indicates that the infant is, on some level, treating novel and original stimuli as different. A lack of longer looking at the novel stimulus relative to the original indicates that the infant is, on some level, treating novel and original stimuli as equivalent. The degree of novelty preference can therefore be compared when novel and original stimuli from the same or different categories. Greater different-than same-category novelty preference when chromatic differences are equated would indicate an influence of categories on infants' perception or cognition. In addition, categorization can be broadly defined as the treatment of discriminably different stimuli as equivalent (e.g., [2]). Therefore, a lack of novelty preference when infants can discriminate between novel and familiar stimuli becomes a clear marker of categorization. This method has provided overwhelming evidence for infant categories, for a wide range of categories such as phonemes, facial expressions, animals, spatial locations, and orientation (e.g., see [2]).

For color, multiple studies have found a categorical response in infants at 4 months using the habituation method (e.g., [3–6]). Bornstein et al. [3] tested infants at 4 months using monochromatic lights, with the difference between the original and novel stimulus equated in wavelength. Infants responded to a change in stimulus that crossed blue-green, yellow-green, and yellow-red category boundaries, but not to a change in stimulus within these categories. There was one exception to this: when infants were habituated to a red wavelength, their interest in the original red stimulus continued at test, most likely due to the salience of red in infancy. Apart from this, infants' recognition of novelty in hue was completely categorical, and Bornstein et al. concluded that

infants categorize blue, green, red and yellow hues at 4 months. Two further studies also provide evidence of a categorical response to color in infants, finding that 4-month-olds fail to recognize the novelty of a color when original and novel colors are from the same blue or green category [4] or from the same red or blue categories after a 5 min delay between habituation and test [5]. In addition, a fourth study indicates that 4-month-old infant's response to chromatic novelty is also categorical across blue-green, red-pink, and blue-purple category boundaries, when same- and different-category colors are equated in color metrics such as the Munsell color system and CIE ($L^*u^*v^*$, 1976) color space [6].

Therefore, a categorical response to color in infancy has now been found in multiple habituation studies, for over 25 different stimulus pairs taken from three different color metrics, and with different versions of the habituation task. In all of these studies, the same-category chromatic differences are known to be discriminable to infants at 4 months. Infants at 4 months are able to discriminate same-category chromatic differences of an equivalent size when tasks do not involve color memory (e.g., color search: [7, 8]), and the same-category chromatic differences were all much greater than chromatic discrimination thresholds at 4 months. In fact, some of the same-category stimulus separations in Bornstein et al. investigation were as much as 20 times larger than the estimated just-noticeable difference for a 4-month-old (see [6]). Even when a luminance difference is intentionally added to maximize the difference between novel and original stimuli [6], 4-month-old infants still fail to respond to the novelty of a color from the same category as the original. Infants' pattern of responding to color on habituation tasks therefore fits the classic definition of categorization that "discriminably different stimuli are treated as equivalent" (e.g., [2]). These studies provide a parallel to adult studies which have used an X-AB task. The X-AB task requires participants to encode an original color and then distinguish it from a novel foil after a delay. Adults are poorer at identifying the original color when the original and foil are from the same category than when they are from different

categories. Infants' pattern of response on habituation tasks is equivalent to this, as they are also poorer at distinguishing between original and novel same- than different-category colors at test. In fact, infants are even more categorical in their response than adults as, at least under some conditions, they fail to distinguish between the original and novel same-category colors at all.

Another method which has been used to investigate both adult and infant color categories is the event-related potential (ERP) technique. This involves measuring electrical activity from the scalp, which is then time locked to an event such as stimulus onset. Event-related potentials have been measured on a visual oddball task which is commonly used in ERP studies of both adult and infant categorization. The visual oddball task involves the frequent presentation of one stimulus (the standard) interspersed with the infrequent presentation of other stimuli (the deviants), and ERP components for standard and deviant stimuli are compared for evidence of change detection. For adults, the categorical relationship of standard and deviant colors affects the latency and amplitude of several ERP components elicited in response to the stimuli. For example, different-category deviants elicit ERP components that peak earlier or are of greater amplitude than same-category deviants, indicating quicker and greater detection of different- than same-category chromatic change (see [9] for review). Category effects in ERPs on a visual oddball task have also been found in infancy [9]. Even at 7-months, the categorical relationship of standard and deviant colors affected infants' ERP components. Category effects were found in ERP components thought to index recognition memory (slow waves) and attentional allocation (negative central). For both, the different-category deviant elicited an ERP component that was more negative than that elicited by the standard color, yet the same-category deviant did not. These findings indicate that, within the context of the frequent repetition of a color, an infrequent different-category color will elicit greater attentional allocation and will be seen as more novel than the frequent color, whereas a same-category infrequent color will not. As in the habituation studies,

the same-category colors were discriminable to infants at 7 months, and therefore the equivalence of the same-category deviant and standard in ERP components of attention and memory indicates electrophysiological markers of infant color categorization. Due to the time course of the negative central ERP component, Clifford et al. study also suggests that infants register the categorical status of a color from as early as 250 ms poststimulus onset. These findings are in line with other ERP studies of categorical responding in infancy, such as phoneme categorization and category learning of cats and dogs (see [9]).

Chromatic search tasks have also been used to investigate infant color categories. In adult studies that have used these tasks, participants are required to search for a colored target that is either from the same or a different category to the colored distracters or colored background. When same- and different-category colors are equated in CIE ($L^*u^*v^*$, 1976) or Munsell color metrics, at least under some conditions, adults are faster or more accurate at searching for targets amongst different- than same-category distracters or backgrounds. The influence of color categories on infants' color search has been investigated by measuring 4–6-month-old eye movements to colored targets presented on colored backgrounds. Infants are significantly faster at fixating a colored target [7] and at initiating an eye movement to a colored target [8] when presented on a different- than same-category colored background. In these infant studies, the chromatic difference between the target and background was equated for same- and different-category color pairs in CIE $L^*u^*v^*$ color space yet are also closely equated when stimuli are converted to the MacLeod-Boynton cone excitation color space. Franklin et al. [8] found this effect of categories on infants' target detection when the target was presented to the left visual field, but not to the right visual field, potentially suggesting that there is a right hemisphere lateralization of categorical perception of color in infancy. This right hemisphere lateralization contrasts with reports of left hemisphere lateralization in the adults' category effect (see [1]), and it appears as though a right-to-left hemisphere switch occurs around the time of color term

acquisition [10]. However, these effects have so far only been tested for in infants across the blue-green category boundary, and recent studies also report a lack of hemispheric lateralization for the effect in adults under some conditions (e.g., [11]). Further research is therefore needed to establish the nature of these effects in both infants and adults and the conditions for the pattern of hemispheric lateralization.

Negative Findings

There is only one published study which fails to find a categorical novelty response in infants [12], and that study tested for a categorical response across the red-orange category boundary using a task which determined whether a novel color “popped out” amongst six instances of a color to which infants had been familiarized. This could indicate that infants do not respond categorically across the red-orange boundary or that the novelty response is not categorical under conditions of “pop out.” There may well be conditions under which infants’ responding is not categorical, and as for adults, the relative strength of the categorical and physical code may depend on cognitive demands. However, it has been argued that an unintended category boundary for one of the same-category stimulus pairs, and the use of an inappropriate illuminant, renders the findings of Gerhardstein et al. unsafe [13]. A second unpublished study has been cited as evidence for a lack of replication of an infant category effect across the blue-green boundary. However, the habituation task that was used failed to detect any response to color in the infants at all, most likely due to particular parameters of the habituation task (e.g., a change from central to peripheral stimulus presentation at test could have detracted attention from the change in color). Therefore, as there was no response to color at all, a categorical effect could not be assessed (see [14] for further discussion). These negative findings, which should be considered as unsafe, are outweighed by the converging behavioral and electrophysiological evidence for a categorical response to

color in infancy. The finding of infant color categories has now been replicated across multiple color category boundaries, using multiple tasks and color metrics, and by several independent research teams.

Alternative Explanations

As outlined above, there is converging evidence that, at least under some conditions, infants’ response to chromatic novelty or recognition memory can be completely categorical. Potential alternative explanations for infants’ response to color in these studies have been considered and ruled out. First, a priori hue preferences are unable to account for the findings as studies have controlled for these (see [14]). For example, same-category stimulus pairs have been sampled from both sides of the category boundary (e.g., [3, 6]), a priori preferences have been recorded and shown not to account for infants’ response (e.g., [6]), and control tasks have also been included (e.g., [9]). Second, potential inequalities in the color metric are unable to account for infants’ response to color. As for studies of adult color categories, there is an issue about which color metric is appropriate to equate same- and different-category colors: using a physical metric (e.g., wavelength), a perceptual metric such as Munsell or CIE ($L^*u^*v^*$), or a cone-opponent color space (e.g., MacLeod-Boynton color space). Importantly, infant color categories appear to transcend this metric issue. Infants’ pattern of response is identical across studies which vary in the color metric used. Additionally, at least under some conditions, infants’ novelty response to color appears completely invariant to the color metric, as distances in any of these metrics do not predict the degree of infants’ chromatic novelty preference or change detection. Infants treat same- but not different-category chromatic differences as equivalent on habituation or visual oddball tasks, irrespective of the size of the same-category chromatic difference. Only the categorical relationship between stimuli can account for this pattern of response.

Theoretical Questions and Future Directions

The converging evidence for infant color categories strongly suggests that there is a nonlinguistic route to parsing the continuum of color into discrete groups. However, there is also convincing evidence that the influence of color categories on adults' cognition and perception is dependent on language and that different languages also vary in how they divide up the color spectrum [see Roberson]. This raises two sets of challenging questions for future research to consider and address. First, what is the relationship between prelinguistic and linguistic color categories? Why do some languages not have color terms for categories that infants have? For example, many of the world's languages do not have separate terms for blue and green, yet infants appear to form separate categories for these. The answer to this question may be in the analysis of the World Color Survey [see TBA]. Multiple analyses of the World Color Survey strongly suggest that, despite variation in color lexicons, there is also striking commonality in how the world's languages divide up the color spectrum. For example, the centers of color categories across languages tend to cluster around particular points in the color space, with distinct clusters for "blue" and "green." It has therefore been suggested by several groups that there are perceptual constraints on how categories form in color lexicons (see [1]). Therefore, although not all languages have separate terms for blue and green, there appears to be a common pressure in the world's color lexicons for separate categories of blue and green to form. One possibility is that this commonality arises because infant color categories partially constrain the world's color lexicons, while local variation arises due to the additional influence of culture and communication [1].

Alternatively, infant color categories and those in language could operate independently from each other but could have similar organizing principles. This raises the question of what happens when prelinguistic and linguistic color categories converge when color terms are learnt. What are the mechanisms of the switch from a nonlinguistic

to a language dominant division of the color spectrum? How do prelinguistic color categories affect color term acquisition? The presence of infant color categories strongly suggests that any difficulty that children have in learning color words is unlikely to be due to a lack of category structure but rather provides support for the argument that there are general attentional, conceptual, and linguistic constraints that make learning color words difficult relative to nouns, but not other adjectives (see [15]). However, it is theoretically possible that color term learning may be more difficult for lexicons which map less well onto the prelinguistic category structure that is there in infancy.

Second, what are the organizing principles of infant color categories? Where do infants get their category structure from? Several theories have been proposed to identify the organizing principles of color categories. For example, it has been proposed that color categories derive from (i) the clustering of colors taken from surfaces in the natural chromatic environment; (ii) reflection properties, with some colors (those that correspond to the unique hues) reflecting incoming light in a much simpler way than others; or (iii) an irregularly shaped perceptual color space combined with basic principles of categorization (see [1]). None of these organizing principles rely on language, and all are contenders for explaining how infants are able to categorize color even before color terms have been learnt. Importantly, color categories may not be inbuilt into our visual system but rather could be a cognitive response to inequalities in our visual system's processing of color. Some hues could be more salient than others, for example, due to having greater maximum levels of saturation or different reflection properties. This could lead to some colors being more informative than others, and inequalities such as these could provide structure for cognition when categorizing. The actual categorical response to color in infants could therefore come from an interaction of perceptual inequalities in color and a general cognitive strategy to categorize. It is well known that categorization is a core part of infant cognition and is essential in helping infants to navigate an uncertain world (e.g., [2]). If

color categories do result in part from general cognitive strategies, differences between humans and animals in the extent of the categorical response to color could arise due to differences in cognition, even if color vision is similar (e.g., baboons; see Weber and Changizi).

These questions on how infant color categories relate to those in language, and on the organizing principles and underlying mechanisms of infant color categories, provide clear direction for future research. Investigations which empirically address such questions will resonate beyond color and will have implications for fundamental questions on how categories are formed, how categories in language and thought interact, and how categories are expressed in the brain.

Inorganic, Hybrid, and Functional Pigments, Fig. 1 Structure of pigments consumption (a) with respect to pigment type and (b) with respect to specific pigments

Definition

Pigments, which have been widely used since prehistoric times, include naturally occurring substances prepared from minerals or their combustion products as well as synthetic compounds produced from appropriate raw materials and also hybrid pigment types derived from organic and/or natural dyes and selected mineral supports including metal oxides, biopolymers, and others. Pigments are insoluble in the surrounding medium and their optical effect arises from selective light absorption. They are classified according to their color, origin, method of production, and the character of the pigment material. Hybrid pigment technology is directly related to the development of new synthesis methods, preparation of functional and also environmentally friendly colorants.

Introduction

This entry presents the main aspects of classification and production technology, broadly

understood, for the most common inorganic pigments. It explains the most important physicochemical and application properties of a wide range of pigments, including white pigments in particular. Also discussed are issues relating to special pigments, including the new category of hybrid or functional pigments.

A clear majority of inorganic pigments are fully suitable for use in products satisfying high levels of consumer demand. Inorganic pigments are commonly used for the production of paints and lacquers, plastics, inks, construction materials, paper, glass, and ceramic products. Total consumption of pigments is presented in Fig. 1, and clearly confirms the greater importance of inorganic pigments with respect to organic ones [1].

The significance of inorganic pigments, relative to organic pigments, is consistently increasing. Inorganic pigments are more chemically inert, insoluble, and resistant to temperature and extreme pH values than organic ones. Characteristic features of inorganic pigments include excellent opacity, good color saturation, and stability. They make it possible to obtain durable and high-quality coatings.

General Information

Pigments are colored materials, which in refined state are also used for the dyeing of synthetic fabrics, rubber, and paper, and which impart color as a result of wavelength-selective light reflection, absorption, or interference. They improve the aesthetic value of certain products, and also have some practical functions (such as protecting metal objects against corrosion by painting, e.g., bridges, ships, cars, trains, and steel constructions).

Pigments are insoluble in oil, water, organic solvents, and resins. They can be classified according to color, origin, method of production, and the character of the pigment material. They are divided according to origin into inorganic and organic, and according to method of production into synthetic and natural. Inorganic and organic pigments differ in many features, such as light and weather resistance, high opacity, color strength, and ease of dispersion. Inorganic pigments usually offer better resistance to light and atmospheric conditions, higher dispersion, and opacity [2, 3].

There are pigments which, apart from coloration, also display luminescence (luminescent pigments) or change color as a function of temperature (thermosensitive pigments). These are used for the production of luminescent or thermosensitive paints.

Pigments can include different components; according to the character of the material from which they are made, they are divided into:

- Homogeneous – made of pigment particles of the same type, e.g., oxides of color metals
- Mixed or hybrid pigments – made by mechanical mixing (vigorous mixing of the dyeing substance with an extender) or by chemical synthesis (organic dyes or pigments grafted onto mineral supports or biopolymer-based supports)

Classification of Inorganic Pigments

Pigments can be classified on the basis of their chemical structure, optical properties, or technological properties.

A detailed classification of inorganic pigments according to their chemical structure and color subgroups is illustrated in Fig. 2.

Properties

Pigments are mainly used for coloration and for endowing specific properties to paint coatings. They are important components of lacquer and paint coatings, influencing their final mechanical properties and resistance; they affect the paints' rheology, stability, and some properties related to application. Those physicochemical properties of pigments chiefly influence the application and technological conditions of their commercial use [3–5].

From the application point of view, the most interesting are functional properties of pigments for specific target demands, including the following:

- Optical properties – color, tinctorial strength, opacity
- Physical – solid state properties – crystalline structure, grain morphology, character of surface, light refraction index, and defined structural properties
- Resistance and protective properties

All of these properties are to some degree determined by chemical structure [3].

The pigment color, shade, opacity, resistance to chemicals as well as viscosity depend mainly on the chemical and crystalline structure, light refraction index, size and shape of particles, and character of the particle surface. The crystalline structure determines such properties as dispersion, rheology, solubility, color strength, and shade.

Exemplary morphological structures of selected inorganic pigments and extenders are illustrated in Fig. 3.

The fundamental properties of inorganic pigments are the following.

- *Color and intensity of coloration*

The color depends on chemical composition and degree of purity, as they define the ability to absorb certain wavelengths and to reflect the complementary color. The tinctorial strength or

Inorganic, Hybrid, and Functional Pigments, Fig. 2 Inorganic pigments classification

color strength is defined as the pigment's ability to change the original color of a given material. This is related to the pigment's introduction to a given material and depends on the degree of refinement, purity, and homogeneity of chemical composition.

- *Opacity*

The opacity (hiding power) depends on the size and structure of pigment particles and on the difference in the light refraction index of the pigment and the binding agent. The covering ability is better when the pigment has small particles and then difference in the light refraction index is significant.

- *Shape and size of pigment particles*

The size of pigment particles is regulated to obtain the optimum visible light scattering. The size of particles has an impact on the stability, coating resistance, and its covering power. The pigment particle size can vary from 1 to 10 μm , and particles of the smallest

diameters ensure higher density and protective properties.

- *Resistance to UV radiation*

Pigments should display the highest possible resistance to light. A change in color, usually brightening or darkening under exposure to visible light or other radiation, is mainly caused by changes in the dispersion of the pigment in the binding agent and changes in that agent.

- *Thermal resistance*

Thermal resistance is of particular importance when paint coatings are made on hot substrates or when dyeing plastic products are subjected to hot processing. The pigments used for such purposes should be resistant to high temperatures.

- *Resistance to chemical agents*

Of particular importance is the pigment's resistance to alkaline and acid agents. A pigment's resistance to the binding agent,

Inorganic, Hybrid, and Functional Pigments, Fig. 3 (a) Particles morphological structure and **(b)** TEM images of commonly known inorganic white

pigments and extenders. (Created based on [3] with permission, Copyright 2013: Vincentz Verlag Publisher)

substrate, and exploitation conditions should also be analyzed. When pigments are mixed their interaction must also be established.

- *Optical properties*

Optical properties of pigments are described by the color and light absorption coefficient. The color is determined by the adsorbed or reflected wavelengths of light.

- *Wettability by binding agent*

Wettability by the binding agent depends on the degree of the pigment particles' refinement, the pigment structure, and the wetting properties of the binding agent. For oil products it is described by the so-called oil absorption number.

- *Toxicity*

Mineral pigments often contain heavy metals, but their presence is not a threat to human health or the natural environment. In the process of production of such pigments the heavy metals are so strongly bonded in the pigment structure that they are not released into the environment. In many countries the content of heavy metals in pigments for use in special products, such as those that are in contact with food, toys for children and cosmetics, is controlled by special regulations specifying admissible heavy metal levels.

Most of the aforementioned physicochemical properties of pigments determine their potential uses. Among the most common types displaying these physicochemical properties are white and black pigments, and more rarely brown, yellow, red, blue, and green pigments.

White pigments – the optical effect of these is achieved by nonselective light scattering; technologically the most important examples are titanium dioxide, zinc white, zinc sulfide, and lithopone.

Titanium dioxide (C.I. Pigment White 6; TiO_2) occurs in three crystalline varieties: brookite (not used as a pigment), anatase, and rutile. Irrespective of the technology of titanium white production, the pigments are characterized by high purity and defined crystallites and particle sizes. To improve the functional properties of the

pigment in a coating, the titanium white surface is modified with different chemical compounds. The attractive features of titanium white pigment include high light refraction index, chemical and physical stability, possibility of regulation of particle sizes, and possibility of surface modification. The crystallites and particle sizes are the main parameters determining the paint properties. The optimum size of TiO_2 crystallites ensuring maximum light scattering, and hence high opacity of paint coatings, is close to $0.23\ \mu\text{m}$. The physical and chemical resistance of pigments contributes to the resistance of a paint coating. The paint coat usually undergo degradation under the influence of ultraviolet radiation, so the addition of substances absorbing UV radiation increases the paint coat's lifetime. Moreover, titanium dioxide has the highest refractive index (2.55 for anatase and 2.70 for rutile) among all inorganic pigments and commonly known extenders. Because of the universal properties of this pigment, it is produced by industrial methods on a wide scale [6, 7].

Production of TiO_2

Titanium white pigments are produced on an industrial scale by two methods: sulfate and chloride.

- Sulfate process – TiO_2 is precipitated from a solution of ilmenite ore by concentrated sulfuric acid; both rutile and anatase can be obtained.
- Chloride process – TiO_2 is obtained as a result of oxidation of titanium tetrachloride (TiCl_4) synthesized by reduction and chlorination of ilmenite ore or rutile sources; only rutile is obtained.

The chloride process is more often used. It is estimated that over half of the titanium white produced worldwide is obtained by this method. Although this process needs higher quality and preliminarily enriched ore and more complex technology, it produces less waste (thus being less burdensome to the environment) and is cheaper than the sulfate method.

Inorganic, Hybrid, and Functional Pigments, Fig. 4 Production of TiO_2 by the (a) sulfate method and (b) chloride method

Inorganic, Hybrid, and Functional Pigments, Fig. 4 (continued)

Sulfate Method

The sulfate method of titanium white production is complex. It is divided into two main technological parts, called the black part (alluding to the color of the ore) and the white part (alluding to the color of white pigment). Each block includes several unit operations.

The idea is to extract TiO_2 from raw titanium ore at elevated temperature by means of concentrated sulfuric acid (85–95%). The most often used titanium ores are ilmenite (FeTiO_3) containing 45–65% TiO_2 , and titanium slag. The prepared ore is mixed with concentrated sulfuric acid, and compressed air is blown through the reactor, as this accelerates etching. The reaction starts above 140 °C and is exothermic, which causes a further increase in temperature to 200–220 °C. The reaction mixture is left for 1–12 h to mature. The mixture is cooled to obtain a porous sinter, and then it is dissolved in water or diluted sulfuric acid. The process is performed at low temperature (below 85 °C), to prevent premature hydrolysis. The solution obtained, the so-called titanium liquor, is reduced with steel

scrap in order to transform Fe^{3+} into Fe^{2+} ions and partly also Ti^{4+} into Ti^{3+} ions. The solution is subjected to sedimentation, and the unreacted substrate is filtered out from the suspension. The content of TiO_2 in the product differs depending on the type of titanium ore: when ilmenite is used it is 8–12%, and when titanium slag is used it is 13–18%. When the temperature is decreased to 10 °C the main by-product of the process – hydrated iron sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) – undergoes crystallization. When titanium slag with a TiO_2 content higher than 75% is used, the stage of iron sulfate crystallization is not necessary. The purified solution is concentrated to 200–250 g TiO_2/dm^3 . Hydrolysis of titanium sulfate is then performed (at 94–110 °C) by diluting the solution and maintaining the suspension at the boiling point. This process influences the size of the product particles and the degree of flocculation. The hydrated titanium dioxide formed is filtered off, washed with water, and subjected to whitening by hydrogen. The hydrated titanium dioxide obtained contains 20–28% sulfuric acid and sulfates. These impurities are removed by filtration

Inorganic, Hybrid, and Functional Pigments, Table 1 Characteristics of commonly known inorganic pigments

Pigment type	Production	Advantages	Disadvantages	Color
Carbon black	Decomposition of carbonaceous precursors	Rich color, color strength, light and weather resistant	Thickens paint, color limits application	Black
$\text{CH}_4 \xrightarrow{\text{temp.}} \text{C} + 2\text{H}_2$				
Titanium dioxide	Synthesized mainly by sulfate or chloride technology (alternatively using sol-gel, hydro- or solvothermal methods)	High opacity and color strength, relatively cheap, very good UV resistance, very high refractive index, good resistance to alkaline solutions, mostly chemically inert pigment	Tendency for agglomeration of primary particles, forms radicals that degrade the binder/polymer matrix	White
$\begin{aligned} \text{FeTiO}_3 + 2\text{H}_2\text{SO}_4 &\longrightarrow \text{TiOSO}_4 + 2\text{H}_2\text{O} + \text{FeSO}_4 \\ \text{TiOSO}_4 + 2\text{H}_2\text{O} &\longrightarrow \text{TiO(OH)}_2 + \text{H}_2\text{SO}_4 \\ \text{TiO(OH)}_2 &\xrightarrow{\text{temp.}} \text{TiO}_2 + \text{H}_2\text{O} \\ \text{TiO}_2 + \text{C} + 2\text{Cl}_2 &\longrightarrow \text{TiCl}_4 + \text{CO}_2 \\ \text{TiCl}_4 + \text{O}_2 &\longrightarrow \text{TiO}_2 + 2\text{Cl}_2 \end{aligned}$				
Iron oxides	Synthesized, obtained as minerals and also prepared from chemical wastes	Light and weather resistant, mostly unreactive	Cannot produce clean shades	Yellow, red, brown, black
$\begin{aligned} \text{C}_6\text{H}_5\text{NO}_2 + 2\text{Fe} + \text{H}_2\text{O} &\longrightarrow \text{C}_6\text{H}_5\text{NH}_2 + \text{Fe}_2\text{O}_3 \\ 3\text{Fe}_2\text{O}_3 + \text{H}_2 &\longrightarrow 2\text{Fe}_3\text{O}_4 + \text{H}_2\text{O} \\ 3\text{Fe}_2\text{O}_3 + \text{CO} &\longrightarrow 2\text{Fe}_3\text{O}_4 + \text{CO}_2 \\ 2\text{Fe}_3\text{O}_4 + 1/2\text{O}_2 &\xrightarrow{\text{temp.}} 3(\gamma\text{-Fe}_2\text{O}_3) \\ 2\text{Fe}_3\text{O}_4 + 1/2\text{O}_2 &\xrightarrow{\text{temp.}} 3(\alpha\text{-Fe}_2\text{O}_3) \end{aligned}$				
Zinc oxide	Chemical or metallurgical synthesis	Excellent heat stability, light and weather resistant, very good UV resistance, anticorrosive properties	Expensive chemical synthesis, tendency to form agglomerations	White
$\begin{aligned} \text{ZnSO}_4 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + \text{Na}_2\text{SO}_4 \\ \text{ZnCl}_2 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + 2\text{NaCl} \\ \text{Zn(CH}_3\text{COO)}_2 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + 2\text{CH}_3\text{COONa} \\ \dots\dots\dots &\dots\dots\dots \end{aligned} \quad \left. \vphantom{\begin{aligned} \text{ZnSO}_4 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + \text{Na}_2\text{SO}_4 \\ \text{ZnCl}_2 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + 2\text{NaCl} \\ \text{Zn(CH}_3\text{COO)}_2 + 2\text{NaOH} &\longrightarrow \text{Zn(OH)}_2 + 2\text{CH}_3\text{COONa} \\ \dots\dots\dots &\dots\dots\dots \end{aligned}} \right\} \text{Zn(OH)}_2 \xrightarrow{\text{temp.}} \text{ZnO} + \text{H}_2\text{O}$				
$\text{ZnCO}_3 \xrightarrow{\text{temp.}} \text{ZnO} + \text{CO}_2$				

(continued)

Inorganic, Hybrid, and Functional Pigments, Table 1 (continued)

Pigment type	Production	Advantages	Disadvantages	Color
Zinc chromates	Synthesized	Anticorrosive properties	Thickens paints, dangerous synthesis with regard to reagent	Yellow
$4\text{ZnO} + 2\text{CrO}_3 + \text{K}_2\text{Cr}_2\text{O}_7 + \text{H}_2\text{O} \longrightarrow \text{K}_2\text{CrO}_4 + 3\text{ZnCrO}_4 \cdot \text{Zn}(\text{OH})_2$				
Ultramarine	Synthesized, seldom obtained as mineral	Rich color	Low stability in acidic environment	Blue
$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 + \text{Na}_2\text{CO}_3 + \text{Na}_2\text{SO}_4 \xrightarrow{\text{sulfur, carbon, temp.}} \text{Na}_{8-10}\text{Al}_6\text{Si}_6\text{O}_{24}\text{S}_{2-4} + n\text{CO}_2 + n\text{SO}_x + n\text{H}_2\text{O}$				
Chromium oxides	Synthesized as native pigments or produced from wastes	Light, weather, acid and alkali resistant, thermal stability	Does not give clear colors	Green
$4\text{CrO}_3 + 3\text{N}_2\text{H}_4 \longrightarrow 4\text{Cr}(\text{OH})_3 + 3\text{N}_2$ $2\text{Cr}(\text{OH})_3 \xrightarrow{\text{temp.}} \text{Cr}_2\text{O}_3 + 3\text{H}_2\text{O}$ $(\text{NH}_4)_2\text{Cr}_2\text{O}_7 \xrightarrow{\text{temp.}} \text{Cr}_2\text{O}_3 + \text{N}_2 + 4\text{H}_2\text{O}$ $\text{Na}_2\text{Cr}_2\text{O}_7 + 2\text{S} \xrightarrow{\text{temp.}} \text{Cr}_2\text{O}_3 + \text{Na}_2\text{SO}_4$				
Cadmium sulfides	Synthesized	High opacity and color strength	Poor weather resistance, very expensive	Greenish yellow, red, deep red
$\text{CdCl}_2 + (\text{NH}_2)_2\text{CS} + 2\text{NH}_4\text{OH} \longrightarrow \text{CdS} + (\text{NH}_2)_2\text{CO} + 2\text{NH}_4\text{Cl} + \text{H}_2\text{O}$				

and washing with water, followed by reduction in the process of whitening, in which most of impurities are removed. On completion of this process the content of colored impurities is of an order of ppm, while the content of sulfuric acid is still significant, at a level of 5–10%.

In the white part the hydrated titanium dioxide is again filtered, washed, and prepared for calcination. When the aim is to produce rutile, the nuclei of rutile and substances favoring transformation of anatase into rutile are introduced, and the process of calcination is performed at ca. 950 °C. When the aim is to obtain anatase, no admixtures are introduced and calcination is performed at a lower temperature. The hydrate formed in the process of calcination is subjected to calcination to remove water and to obtain TiO₂. When rotary filters are used the content of titanium dioxide in the product is 30–40%, but when pressure rotary filters or automated filtration press are used the content reaches 50%.

A schematic presentation of the sulfate method of titanium white production is given in Fig. 4, and the reactions at each step are listed in Table 1.

Chloride Process

In the chloride process the substrates are rutile or enriched titanium ore containing over 90% TiO₂. This method is more modern, more technologically advanced and less burdensome to the natural environment; however it enables the production of rutile only. The problems related to this method are the high temperature of the process; the aggressive medium; the toxicity of chloride, carbon monochloride, and titanium tetrachloride; and the risk of uncontrolled emission of chlorine gas. The advantages of this process are that the pigments obtained have higher resistance to light and are brighter than those obtained by the sulfate method.

The substrate introduced into the reactor is maintained in the fluid phase by a flux of air. The substrate is heated to 650 °C and then refined coke is introduced in the amount of 250–300 kg per tonne of TiO₂. The substrate should be dry and should not contain too small particles that would be carried by the stream of forming TiCl₄ and could contaminate the product. Burning coke causes an increase in temperature to about 1000 °C. In these conditions the introduction of

chlorine and continuous supply of titanium ore (substrate) and coke begin.

The reaction leads to the formation of titanium tetrachloride gas, which is the main product, and by-products including chlorides of contaminating metals, e.g., iron, manganese, and chromium, which together with the unreacted substrate are separated from the reaction mixture by fractional condensation. The formed titanium tetrachloride and the accompanying chlorides are distilled off from the fluid bed. These gases are then cooled with liquid TiCl_4 . Some of the metal chlorides (mainly iron chloride) can be deposited on the surface of TiCl_4 upon crystallization. To prevent this, the chlorides are condensed off. In this way the impurities of TiCl_4 are removed. Cooling is carried out in stages. First the gases are cooled to a temperature below 300°C . Then the chlorides co-occurring with titanium tetrachloride are separated by condensation or sublimation. After this stage the gas is mostly composed of TiCl_4 and is cooled to a temperature below 0°C , at which condensation of TiCl_4 takes place. The raw titanium tetrachloride is carefully purified, at first by the chemical method to separate the substances that could not be removed upon distillation, e.g., VCl_4 , VOCl_3 , and then by vacuum distillation, which gives highly pure TiCl_4 . The pure titanium tetrachloride is evaporated and combusted in a stream of oxygen or air to obtain TiO_2 and chlorine. The reaction is weakly exothermic and needs a high temperature in the range $900\text{--}1400^\circ\text{C}$. The pigment obtained with a mixture of gases (Cl_2 , O_2 , CO_2) is cooled and then separated by an indirect or direct method. The stream of gases is recirculated to the cooling zone of the furnace and to the chlorination stage.

A schematic presentation of the chloride process of titanium white production is given in Fig. 4, and the reactions at each stage are listed in Table 1.

After cooling, titanium dioxide obtained via either the sulfate or chloride method is ground using a wet or dry method and dispersed in water. It can be subjected to surface modification with hydrated oxides, e.g., silica, alumina, or zirconia, to obtain varieties of pigment for special applications. The main aim of the inorganic treatment is to improve the pigment's stability,

reactivity, and its dispersibility. The treatment is carried out in the water phase, and solutions of substances used to modify the particles of titanium dioxide are added in a defined sequence or simultaneously. By regulating the pH of the suspension, hydrated oxides are precipitated on the surface of the pigment particles. The form of the oxides strongly depends on the conditions of precipitation. Alumina, silica, zirconia, or other oxides do not occur in the pigment as an admixture, but as a molecular layer bonded to the pigment surface. After the treatment the pigment is filtered again, dried, and grounded. The product is packed and stored.

Other alternative methods of TiO_2 production, which allow the control of process parameters as well as the physicochemical and useful properties of the products, include the sol-gel, hydro- and solvothermal methods, and chemical vapor deposition.

Sol-Gel Method

In a typical sol-gel process, a colloidal suspension or sol is formed as a result of hydrolysis and polymerization of precursors, which are usually inorganic metal salts or organometallic compounds such as metal alkoxides. Polymerization and loss of solvent lead to conversion of the liquid sol to a solid state gel phase.

The sol-gel method is based on hydrolysis and condensation of metal alkoxide or metal salt. The main process is the reaction of the metal chloride with metal alkoxide or organic ether acting as oxygen donors, according to the Eqs. (1, 2):

In these reactions, M–O–M bond formation is promoted by condensation between M–Cl and M–OR, according to Eq. (3):

In the reaction with ether (4) metal alkoxide is formed as a result of alcoholysis with M–Cl:

At room temperature these reactions are slow, and oxide formation is usually favored by an elevated temperature in the range 80–150 °C. The main reaction (5), between metal chloride and metal alkoxide, takes place at room temperature.

An important advantage of the sol-gel method is the possibility of obtaining TiO₂ particles of nanometric size and controlled shape.

Hydrothermal and Solvothermal Methods

The method of hydrothermal synthesis is commonly used for obtaining titanium dioxide with small-diameter particles for the ceramic industry. TiO₂ nanoparticles are obtained during hydrothermal processing by peptization of titanium precursors with water. The hydrothermal method is commonly used for the production of different morphological forms of TiO₂ such as nanotubes, nanowires, and nanorods.

The solvothermal method is very similar to the hydrothermal method – the difference is that in the former an anhydrous solvent is used instead of water. The range of temperatures can be much greater than in the hydrothermal method, and depends on the boiling point of the organic solvent used. In the method of solvothermal synthesis it is easier to control the size, shape, and crystallinity of TiO₂ nanoparticles than in the hydrothermal case. The solvothermal method is regarded as a versatile method for the synthesis of nanoparticles with narrow particle size distribution.

Chemical Vapor Deposition

Chemical vapor deposition (CVD) is a method for the thermo-chemical processing of materials. The idea of the method is to deposit thin films on a given material to change its physical, chemical, or mechanical properties. The reaction chamber is

charged with titanium precursors, mostly in the gas phase; there on a hot substrate the chemical reactions take place. Usually CVD methods require high temperatures of 900–1100 °C or higher, necessary for film formation, and this condition significantly restricts the use of these methods. In order to obtain the target products, different gas or liquid substrates (precursors) are used, e.g., halogens, chlorides, carbonyls, and volatile organic compounds of titanium.

The wide range of production methods, as well as the outstanding physicochemical and utilizable properties of TiO₂, makes this pigment an extremely attractive product in the paint and lacquer industries.

The greatest amount of titanium white is used for the production of paints. Thanks to a very high light refraction index the paint coatings containing titanium dioxide are intensely white and have high opacity, which means that only small amounts of TiO₂ are needed to produce an excellent white opaque coating. Titanium white also increases the coating durability and ensures high covering power; this means that the coating can be thinner, which improves its functional properties. This pigment is used to obtain high quality lacquers, both white and in pastel colors in mixtures with other pigments and emulsion paints. Paint production uses a large variety of titanium white pigments: rutile, anatase, pigments with modified and unmodified surface, or pigments modified for special needs. The type of pigment depends on the type of paint and its application. For external use (paints exposed to sunlight) rutile varieties are used, while for indoor applications anatase is preferred. Anatase varieties with lower resistance are used in cheap dispersive paints, in self-cleaning paints and in paints for road markings. Rutile varieties have much wider use and can be applied in all types of paints.

TiO₂ is also used for the production of printing inks; less than 3% of global production of titanium white is used for this purpose. TiO₂ pigments in printing inks ensure opacity and high brightness of the coating. Because of the thinness of printing coatings, TiO₂ pigments used for this purpose should have a narrow particle size distribution and should not contain agglomerates. The proper

choice of pigment is very important as it affects many properties of the ink, such as luster, color, covering power, susceptibility to sedimentation, wearing, and rheological properties. The varieties of titanium white pigment should be chosen depending on the final intended use of the ink.

The second best known and widely used white pigment is *zinc oxide* (C.I. Pigment White 4; ZnO). This pigment is produced especially by a metallurgical process based on zinc ore calcinations [8].

Metallurgical Process

Zinc oxide products are divided into:

- Type A – obtained by a direct process (American process)
- Type B – obtained by an indirect process (French process)

In the direct (American) process, zinc ore is reduced by heating with the addition of coal (e.g., anthracite) and then oxidation of zinc vapors in the same reactor in one production cycle. This process was proposed by Samuel Wetherill.

In the indirect (French) process, metallic zinc is molten and evaporated at about 907 °C. Immediate reaction of zinc vapors with oxygen from the air gives ZnO. Zinc oxide particles are transported through a cooling channel and collected at a station of cyclones and sock filters. This process was popularized by LeClaire (France) in 1844, and since that time it has been called the French process. The product is obtained in the form of agglomerates of mean size from 0.1 to a few μm . The particles of ZnO have mainly spheroidal shape. The French process is carried out in vertical furnaces. Zinc oxide type B shows higher purity than type A.

Of great importance in the technology of production of ZnO with defined physicochemical and structural properties are the chemical processes described below.

Controlled Precipitation

Controlled precipitation is a widely used method for the synthesis of zinc oxide, as it enables the

obtaining of products with reproducible properties. The idea of the method is to perform a fast and spontaneous reduction of zinc salt with a reducing agent that would stop the growth of particles at a certain size, followed by precipitation of ZnO precursor from the solution. At the next step the precursor is subjected to thermal treatment and grinding. Breaking up of the agglomerates formed is very difficult, so the calcined powders show a high level of agglomeration. The process of precipitation is controlled by such parameters as pH, temperature, and time of precipitation. The most important zinc precursors in chemical processes are zinc acetate and zinc hydroxide. A necessary stage of this process is the calcination of hydrated ZnO at above 120 °C (see Table 1).

Mechanochemical Process

The mechanochemical process is a cheap and simple method for the synthesis of nanoparticles on a large scale. It is based on high-energy dry milling, which initiates a reaction upon ball-powder collisions in a ball-mill at a low temperature. The main difficulty in this method is the uniform grinding of the powder and reduction of grains to a target size. This size decreases with increasing time and energy of milling. Unfortunately, a longer time of milling leads to the appearance of increasing quantities of impurities. The benefits of this method are the low cost, small particles, and limited tendency to form agglomerations, as well as the highly uniform crystalline structure and morphology.

The initial materials used in this method are mainly anhydrous ZnCl_2 and Na_2CO_3 . The reactor is charged with NaCl, which is the reaction medium and which separates the forming nanoparticles. The zinc precursor formed – ZnCO_3 – is subjected to calcination at a temperature in the range 400–800 °C.

Other significant methods for the synthesis of zinc oxide are the hydro- and solvothermal methods and synthesis of morphologically defined particles in emulsion and microemulsion systems, the same as in the case of TiO_2 [8].

Besides TiO_2 and ZnO, commonly known white pigments are *lead white* (C.I. Pigment

White 1; $2\text{PbCO}_3\text{Pb(OH)}_2$) and *zinc sulfide* (C.I. Pigment White 7; ZnS).

Black pigments – the optical effect of these is achieved by nonselective light absorption; among this group of pigments the most common are carbon black and black iron oxide.

The most often used black pigment is *carbon black* (C.I. Pigment Black 6, 7, 8). The majority of carbon black types used as pigments have highly developed surface area, which means that their oil absorption numbers are high. Their high surface activity is responsible for poor wettability, the effect of flotation, and adsorption of paint components on the surface. Carbon black is an inorganic pigment, but it has many properties of organic ones. It is composed of carbon. The wide range of pigments depends on the types of their precursors and the methods of their production. The paint industry uses only modest amounts of black pigments when compared to the rubber industry. In the production of rubber for tires, carbon black not only provides color, but also increases mechanical strength. Black pigments based on carbon black have excellent resistance to light and solvents, although certain solvents can extract some colored contaminants from cheap types of pigments. Black pigments show excellent chemical and thermal stability. The intensity of black depends on the size of the particles: the smaller they are, the more intense the color.

A very attractive black pigment is also *iron oxide* (C.I. Pigment Black 11; Fe(II) and Fe(III) oxide; FeO , Fe_2O_3). In natural form it is found as magnetite (also maghemite, hematite, goethite, lepidocrocite – Fig. 5), which can be used as a pigment, although most iron oxide black pigments are synthesized. Iron oxide is a cheap inert pigment of excellent chemical resistance, insoluble in organic solvents and with excellent durability, though unfortunately it also has limited thermal stability and low tinctorial strength. This group of pigments also includes *graphite* (C.I. Pigment Black 10), formed by crystallization of carbon in hexagonal form.

Color pigments – the optical effect of these is achieved by selective light absorption often in combination with selective scattering; examples include brown, yellow, red, blue, and green pigments.

Brown pigments, of which an example is brown iron oxide (C.I. Pigment Brown 6 synthetic and 7 natural; Fe_2O_3), naturally occurs as burnt sienna or burnt umber. Different shades can be obtained depending on the presence of impurities, in particular manganese oxide. These pigments are more often used for artists' paints than for commercial paints. They have low tinctorial strength. The synthetic pigments give an intense brown color with excellent resistance. They are not widely used for paint production, as similar

Inorganic, Hybrid, and Functional Pigments,

Fig. 5 Typical forms of iron oxide-based pigments

shades can be obtained by mixing cheaper pigments.

Lead chromates (C.I. Pigment Yellow 34, Orange 21; $\text{PbCrO}_4/\text{PbSO}_4$; orange $\text{PbCrO}_4 \cdot \text{Pb}(\text{OH})_2$) are a good example of yellow pigments. The pigments can be composed of pure lead chromate or of a mixture of lead chromate and lead sulfate. They give colors from green-yellow to orange. Chrome yellow displays excellent opacity, a low oil absorption number, high brightness of shades, and high color saturation, which make it an ideal pigment for the production of paints in a wide gamut of yellow shades. Yellow pigments have very high resistance to solvents and relatively good thermal stability, which can be improved by chemical stabilization. They are sensitive to alkaline compounds and to acids, which cause them to fade. Their resistance to light is usually satisfactory, although they can become slightly darker under exposure to light. These drawbacks can be counteracted by surface modification with such materials as silica, antimony, aluminum oxide, or different metals. Other yellow pigments are cadmium yellow (C.I. Pigment Yellow 37, 35 lithopone; CdS ; lithopone – CdS containing ZnS) and yellow iron oxide (C.I. Pigment Yellow 42 synthetic, 43 natural; $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, or more exactly $\text{FeO}(\text{OH})$).

Excellent functional properties, such as thermal and chemical stability, and resistance to solvents are provided by red iron oxides (C.I. Pigment Red 101 synthetic, 102 natural; Fe_2O_3), which belong to the category of red pigments. They are also highly opaque and have quite

low tinctorial strength. Despite the serious drawback of its dull brown-red shade, it has the great advantage of low cost.

Ultramarine (C.I. Pigment Blue 29, Violet 15; general formula $\text{Na}_7\text{A}_{16}\text{Si}_6\text{O}_{24}\text{S}_3$), which belongs to the group of blue pigments, has attractive features, including dazzling color and pure shade that can vary from pink, through violet to green. It is also characterized by excellent thermal stability, resistance to solvents, and good resistance to light and alkaline compounds. It is not resistant to acids, and thus it cannot be used in exterior paints. Other well-known blue pigments are Prussian blue (C.I. Pigment Blue 27; $\text{FeK}_4\text{Fe}(\text{CN})_6$) and cobalt blue (C.I. Pigment Blue 36; $\text{Co}(\text{Al,Cr})_2\text{O}_4$).

Last in sequence but not least in importance are the green pigments, such as green chromium oxide (C.I. Pigment Green 17; Cr_2O_3) and hydrated chromium oxide (C.I. Pigment Green 18; $\text{Cr}_2\text{O}(\text{OH})_4$). These pigments have an opaque shade, good opacity but low tinctorial strength. They also offer excellent thermal stability, and chemical resistance to solvents and light [2, 9, 10]

Because of their specific properties, inorganic pigments are used mainly in the paint and lacquer industries. However, in order to meet set requirements for the final products (paints and coatings), they must be formulated with other additives which do not provide any staining or opacity. These additives are known as extenders (Table 2). They may be used to change typical pigment properties as well as specific functions [3, 11].

A special group of inorganic pigments consists of *pigments with luster (mirror effect)* and

Inorganic, Hybrid, and Functional Pigments, Table 2 Example of pigment extenders

Extender type	Formula	Uses
Calcium carbonate	CaCO_3	Additive for paints containing solvent, printing inks
Silica	SiO_2	Additive for rheology and thixotropy control, anti-settling, thickening and anti-sagging agent
Talc	$\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$	Gives high hiding power and a stain finish, provides a matting effect and decreased moisture permeability
Barytes	BaSO_4	Additive for waterborne paint systems
Kaolin	$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$	Decreases viscosity
Mica	$\text{AB}_{2-3}(\text{Al,Si})\text{Si}_3\text{O}_{10}(\text{OH})_2$; A = K, Na, Ca; B = Al, Fe, Mg, Li	UV and chemically resistant, improves water resistance, provides pearl effect

luminescent pigments as well as **hybrid pigments** [12–16]. The first group of these special pigments includes the following:

- **Metallic pigments** (only inorganic) contain lamellar metal particles of high refraction index, e.g., flakes of copper, gold, aluminum.
- **Pearlescent pigments** contain transparent lamellar particles, responsible for a pearl shine, which is the result of multiple reflections from particles oriented in parallel; examples include specially treated alkaline lead carbonates, bismuth oxychloride, and titanium dioxide supported on mica.
- **Interference pigments** – here the optical effect is a result of the thickness of the oxide layer deposited on supports (similarly as in pearlescent pigments); examples are oxides of iron or chromium supported on mica; pigments in this group also display opalescence.

Also very important are luminescent pigments, including:

- **Fluorescence pigments**, of which the optical effect is based on selective absorption of light and simultaneous luminescence, and is initiated by high-energy radiation from the ultraviolet or shortwave visible range; examples are radioactive luminescent pigments.
- **Phosphorescence pigments** (only inorganic) – here the optical effect is based on selective light absorption and scattering followed by delayed luminescence, and is also initiated by high-energy radiation from the ultraviolet or shortwave visible range; examples are zinc sulfide and alkaline earth metal sulfides “dotted” with heavy metal ions.

Hybrid Pigments

Recently, much interest has been paid to the synthesis of hybrid pigments. They can occur in four main combinations: organic/organic, inorganic/inorganic, organic/inorganic, and organic/bioorganic. This group of pigments includes those obtained on the basis of organic dyes and oxide supports including among others silica, titania, or alumina. Substances of this type are

obtained mainly as a result of adsorption of organic molecules on the synthetic or mineral oxide support. Adsorption of organic compounds such as organic dyes is determined first of all by the type of interactions (covalent bonds, electrostatic force, hydrogen bonds, etc.) and the character of the inorganic support (SiO_2 , TiO_2 , $\text{SiO}_2\text{-TiO}_2$, Al_2O_3 , aluminosilicates and carbonaceous materials), among other things its surface properties and dispersion abilities [14–27].

The most often used selective adsorbent of organic dyes is silica synthesized by the sol-gel method. Alternative supports for SiO_2 obtained by this method are the silicas synthesized in the precipitation reaction from water solutions of lithium group alkali metal silicates, mainly sodium silicate. A large group of selective adsorbents or supports consists of mineral substances such as kaolin and montmorillonite. The core of pigment composites can also consist of biopolymers of natural origin (chitin, chitosan, lignin) or synthetic ones.

Hybrid pigments of this type can be obtained in different colors depending on the color of the initial dye. They show many advantages over conventional pigments. The particle size of such pigments depends on those of the initial support. Moreover, from the same core it is possible to get pigments with the same particle size, density and surface properties, but differing in color and hue.

Pigments Obtained by Grafting of an Organic Dye to a Modified Oxides Surface

Such pigments are composed of a core that is a fine powder – SiO_2 , TiO_2 , Al_2O_3 , etc. – and an organic dye chemically bonded with the oxide surface by a coupling agent, e.g., aminosilane. They show high color strength, excellent durability, and resistance to solvents, water, temperature, and light. Their structure can be described by the formula:

where:

S is the support;

CB is a coupling bridge – an alkyl group (3–6 carbon atoms) containing –NH– or –NHCO– in a chain like (for example):

Inorganic, Hybrid, and Functional Pigments, Fig. 6 Mechanism of hybrid pigment formation by adsorption of organic dye onto aminosilane-functionalized

oxide support. (Created based on [28] with permission, Copyright 2013: Elsevier Publisher)

$-\text{CH}_2\text{CH}_2\text{CH}_2-$, $-\text{NH}-\text{CH}_2\text{CH}_2-\text{NH}_2$,
 $-\text{CH}_2\text{CH}_2\text{CH}_2-\text{NHCO}-$, $\text{R}-\text{N}=\text{CH}-$,
 $\text{R}-\text{NH}-\text{CH}_2-$ or $\text{R}-\text{NHSO}_2-$,
 D is the organic dye.

The most popular inorganic support for hybrid pigment formulation is silica. Hydrophilic silicas are usually colorless and have silanol groups on the surface. These species can react with many functional groups through covalent bonds. The process of dyeing of these silicas is multistage. At first silica reacts with a coupling agent in order to bind a compound selectively reacting with a given dye, and then the dye (reactive, acidic, or basic) reacts with the coupling agent (e.g., silane) to give silica particles with covalently bonded dye. The dye permanently bonded to the silanol coupling agent cannot be leached by a solvent, which leads to reduced toxicity of the components of a paint or ink.

The sequence of reactions in this method is shown schematically in Fig. 6. The sequence includes modification of the oxide surface with 3-aminopropyltriethoxysilane in order to introduce amino groups, which in the subsequent process react with the reactive dye (e.g., C.I. Reactive Blue 2) to give dyed silica particles [28].

Through simple and economical processes it is possible to obtain colored particles used as pigments for inks. These inks show high resistance to water and temperature, and have lower toxicity. The inks can be made in a wide gamut of colors and can be used for printing on foil, smooth or coated paper.

This process can be also realized by multistep synthesis of a chromophore on the surface of an inorganic support.

The pigment synthesis involves modification of the support surface – which becomes the core

of the pigment – with an aminosilane coupling agent to introduce surface amino groups and then bonding the dye with amino groups. For this purpose silicas of small diameters are used, as when silica particles are small the area of contact is usually larger, which is beneficial for mixing with other materials.

Pigments Obtained in the Process of Silica Synthesis

Pigments of this type are obtained with silica (or other oxide material) synthesized in a process of hydrolysis and condensation of tetraethoxysilane (TEOS) in a mixture of ethanol/water/ammonia and in the presence of cationic dyes such as C.I. Basic Blue 9 (Fig. 7), additionally treated with, e.g., silane coupling agents in order to increase its adhesion to oxide material surface.

The initial dye solution is prepared in a water medium and is then filtered off through a suitable membrane. In order to synthesize inorganic particles containing a dye, the silica sol and dye solution are mixed to obtain a permanent product. Often the whole amount of the dye used in the process is incorporated into the structure of the pigment, as indicated by a colorless solution remaining after the process. The color particles are filtered off and washed with distilled water until no dye is left in the filtrate.

Retention of dye in the support particles is tested by dispersion in ethanol or acetone, followed by ultrasound treatment and centrifugation. This procedure is repeated a few times to check the stability of the bonding of the dye to the support surface.

There is also interest in combining the functional features of inorganic pigments (TiO_2) or their derivatives ($\text{TiO}_2\text{-SiO}_2$) with selected dyes

Inorganic, Hybrid, and Functional Pigments, Fig. 7 Modification of the pigment and binding with the silica surface

used in the food and/or pharmaceutical industries (e.g., C.I. Food Yellow 4, C.I. Food Blue 5:2, C.I. Food Red 9) [16]. An example mechanism of synthesis of such a hybrid pigment is illustrated in Fig. 8.

Such a combination makes it possible to obtain a homogeneous hybrid system, which is a great advantage from the application point of view, as separate introduction of dye and pigment at the stage of drug formulation (e.g., tablets) is no longer needed and problems with their steric and electrokinetic stability are eliminated.

Colored Bioorganic-Based Hybrid Pigments

Besides various type of inorganic materials used as supports of organic dyes there is also a valuable group of naturally occurring biomaterials such as spongin-based systems. Among them, there are different kinds of organic substances, which skeleton of some sponges can be built of: chitin, spongin, and collagen. Spongin is a biopolymer of still unknown chemical structure, but seems to be a naturally occurring hybrid between collagen and keratin-like proteins. From a practical point of view, the properties and architecture of spongin play a key role and are consequence of its structure. The organic chemistry of sponges is also the focus of intense research because they have been known to contain active biomolecules, which are of therapeutic and pharmaceutical value. Thousands of sponge-derived bioactive metabolites have been isolated and identified so far [29, 30]. Most bioactive compounds from sponges belong to anti-inflammatory, antitumor, immuno- or neurosuppressive, antiviral, antimalarial, antibiotic, cytotoxic, cytoprotective, enzyme-inhibitory, or antifouling class. That is why, the utilization of materials of natural origin like structural proteins – spongin, has been gaining increasing scientific attention. Key features contributing to the popularity of these biomaterials include biodegradability, ecological safety, low cost, high compatibility with the environment and renewability.

Recently, natural dyes are widely studied compounds in modern science and new information about their anticancer, anti-inflammatory, and antioxidant properties are published

[31, 32]. Natural colorants are usually obtained by means of aqueous extraction of plant material; the use of solvents is less common as substantial amounts of plant material have to be extracted. As a result of the nonselective extraction process, natural colorants usually contain a number of different color-providing chemical substances. The classification of a dye plant or animal source to a certain group of colorant usually is based on the properties of the most important species of dye present in the extract.

Natural colorants have some disadvantages as compared to synthetic ones, as they are more expensive and less stable, susceptible to degradation affected by light, pH, temperature, sulfite, ascorbic acid, and enzymes [33]. Natural dyes are renewable and sustainable bioresource products with minimum environmental impact, biodegradable, and nontoxic [34]. They find applications in food and textile coloration, as pH indicators, in cosmetics, pharmaceuticals, or in dye-sensitized solar cell production [35]. However, the most important limitation reported is the low bio-distribution and bioavailability as well as instability. Therefore, adsorption of these natural compounds onto biopolymers support improves their stability and enables use of their antibacterial and antiradical properties in further applications.

There are different groups of natural dyes: anthraquinones, flavonoids (including anthocyanins), or porphyrins. According to their chemical structure they can be divided into several classes, presented in Fig. 9.

Carmine, also called C.I. Natural Red 4 or cochineal, is a dark red dye of animal origin [36]. It can prevent coronary artery disease, plays a role in Alzheimer's disease treating, exhibits cancer chemopreventive activity, and is used in drug delivery products [37].

Anthocyanins are a group of plant dyes belonging to the flavonoids, with a polyphenol structure. Different factors affect the color and stability of these compounds, thus their molecules are highly unstable and easily susceptible to degradation under the influence of pH, temperature, ionizing, UV and solar radiation, the presence of copigments, metallic ions, enzymes, oxygen, and

Inorganic, Hybrid, and Functional Pigments, Fig. 8 Mechanism of C.I. Food Blue 5:2 interactions with $\text{TiO}_2\text{-SiO}_2$ surface (Created based on [16] with permission, Copyright 2013; Elsevier Publisher)

Inorganic, Hybrid, and Functional Pigments, Fig. 9 Types of natural dyes with the examples

ascorbic acid [33]. Anthocyanins have electron-donating abilities hence they have great potential for application as sensitizers in photoelectron-chemical dye-sensitized solar cells [38]. In food, cosmetics, and medicines they serve not only as a colorant but also their wide range of bioactive properties and health benefits is exploited. The antioxidant, antibacterial, anti-inflammatory, antiviral, antifungal, chemopreventive, anticancer, and antimutagenic properties of anthocyanins are well known and described in literature [39, 40].

Chlorophyllin, a porphyrin-like structure dye of plant origin is a precursor of chlorophyllin whose stable macrocycle structure affect the relative thermal stability. This above-mentioned feature as well as water solubility (in contrast to chlorophyll), nontoxicity, and numerous bioactive properties cause the great potential of application for chlorophyllin. Recent studies reveal antioxidant, antimutagenic, and anticarcinogenic properties, because of the ability to bind a planar

compounds such as heterocyclic amines, dioxin, aflatoxin, and benzo[a]pyrene [41, 42]. It also should be mentioned that sodium copper chlorophyllin is used as a dietary supplement, in food, drugs and cosmetics, in textile dyes, as an internal deodorizer and as a natural wound healer [43, 44].

Other porphyrin-like structure dyes include phthalocyanines. Because of their structure they exhibit unique properties: high redox activity; high molar absorption coefficient (light-absorbing electron donors); thermal stability; oxidant, acid, and alkali resistance as well as high reactivity. These features enable to use phthalocyanines in electronics and sensor application, as a dyes and catalysts or for solar cell production [45].

Special type of phthalocyanines include metal phthalocyanines, which exhibit high catalytic activity (in a so-called biomimetic catalytic system) even at ambient conditions, moreover they are relatively easy to synthesize and commercially

available [46, 47]. However, one limitation of these compounds is that they are inconvenient to use, since they are generally available only as powder, in solution (which hinders their separation from the solution and catalyst recycling) or in the form of thin film [48, 49]. A better strategy for their practical use might be to attach them to a suitable support material. Adsorption of metal phthalocyanines on a solid support is an effective way to remedy the drawbacks of the homogeneous catalyst and enable the creation of a heterogeneous system (possibility of reutilization, increase in the surface area of the catalyst).

Mentioned dyes can be easily adsorbed onto the surface of different supports including functional biopolymers. In comparison with other methods this process is fast, facile, takes place in mild conditions, and is broadly applied for dyes. That is why, the preparation of the spongin/dye hybrids allows to combine the functional properties of the dyes with the thermally and mechanically resistant natural support, and enables designing of products with unique physicochemical properties and the possibility of finding interesting application, especially when using natural and synthetic dyes with such properties as: antioxidant, antibacterial, and catalytic.

Preparation of such spongin/dyes systems require specific process parameters control including concentration of the adsorbate solution, the pH and the contact time of the reagents. The higher dye concentration and duration of adsorption, the higher amount of dye adsorbed onto spongin should be expected. Nevertheless, the crucial parameter is pH. This is related to the presence of different forms of dyes depending on the different pH values (see Fig. 10). Moreover, pH affects the nature of adsorbent/adsorbate interactions.

The presence of additional ions (Na^+ and Cl^-) is also a key aspect that affects the efficiency of dyes adsorption onto spongin supports. According to the surface chemistry theory, if there is an attractive electrostatic interaction between adsorbate and adsorbent, then an increase in ionic strength should cause a decrease in the

adsorption capacity of the adsorbent. The converse is found in case of repulsive interaction; increasing ionic strength affect an increase in adsorption capacity, especially when the concentration is high. The presence of additional ions from salt in the medium decreases the repulsion between adjacent dye particles, allowing the adsorbed molecules on the surface to be closer to each other [51, 52].

The realization of the adsorption process, e.g., of copper phthalocyanine onto spongin is promoted by acidic pH, which affect the interaction between dye and spongin skeleton. CuPC have in their structure functional groups (sulfonic) capable for dissociation. Spongin, as a protein material is built of several amino acids with characteristic amino groups ($-\text{NH}_2$), which could be protonated into cationic form ($-\text{NH}_3^+$). Therefore, the interaction between oppositely charged functional groups is possible (Fig. 11).

The differences in the amount of adsorbed dyes may be caused by many factors. Attention should be given to the chemical structure of the dye, its molecular weight or the number, and reactivity of functional groups.

Because of its nontoxicity and antiradical properties naturally occurring anthocyanin has a potential for the utilization as a harmless coloring material. Its color instability under, for example, light irradiation limits its practical use. To the wider use of the anthocyanin, the immobilization on the inorganic host for an easy handling as well as the improvement of the stability is required. The impregnation of spongin skeleton with antioxidant substances could have a positive effect in both application areas, due to free radical scavenging properties, as in the case of anthocyanin dye. The adsorbed anthocyanin exhibits antioxidant properties at a level compared with dye solution (Fig. 12). This could provide a better chemical system in terms of stability without loss of bioavailability.

Numbers of bioactivities are also ascribed to chlorophyllin such as, e.g., antibacterial properties. The basic advantage of the spongin/chlorophyllin systems, in comparison to pure dye should be its insolubility, which provides the

Inorganic, Hybrid, and Functional Pigments, Fig. 10 Different forms of anthocyanins, depending on pH and possible interactions of anthocyanin with spongin at different pH. (Created based on [50] with permission, Copyright 2021: Elsevier Publisher)

Inorganic, Hybrid, and Functional Pigments, Fig. 13 Schematic representation of BPA, phenol, chloro- and fluorophenol degradation. (Created based on [54] with permission, Copyright 2021: Elsevier Publisher)

possibility of reusing it. It is important in terms of potential application, among which attention should be given to preparation of wound dressing.

On the other hand, copper or iron phthalocyanine adsorbed onto spongin may exhibit catalytic properties in organic compounds degradation [53, 54]. The catalytic properties of CuPC are retained in combination with spongin and such a material can be utilized in the combined approach of degradation that involves photochemical systems based on photosensitizers absorbing UV light (CuPC), which works as catalyst and external oxidant, H_2O_2 , which form strong oxidizing species, like $OH^\cdot$. Exemplary mechanism of interaction and effectiveness of phenol-based pollutants is presented in Fig. 13.

All of the above mentioned confirms the excellent properties of spongin skeleton as a dye adsorbent, requiring no special preparation of a sponge as well as mild conditions of adsorption process. Moreover, the benefits of spongin, like three-dimensional, anastomosed architecture, their affinity to different structures of dyes, and high sorption capacity make this material a promising candidate for catalyst support. The high sorption capacity is an effect of the structure of skeleton as well as chemical composition of spongin. The adsorption of selected dyes on the surface of marine sponge skeleton may be conducted using relatively simple method with high efficiency and

this process may be controlled by adjusting the basic parameter.

It was proven that properties of functionalized spongin affect the application of this material. Spongin preserves an important property of immobilized dyes and provides chemical and mechanical improvements to the produced material. Hence, novel, functional dye/biopolymer hybrid materials exhibit antioxidant, antimicrobial, and catalytic properties.

Summary

Technologies for the production and application of a wide range of inorganic, hybrid, and multifunctional pigments are closely interrelated and are constantly being developed. In an era in which many branches of industry are undergoing dynamic development, there is a need to improve and obtain new compounds of various kinds, including hybrid, multifunctional pigments, with specific physicochemical and application properties. New trends in the development of pigments relate mainly to:

- The introduction of new pigments or improvement of the properties of existing ones
- Broadening of the assortment and range of uses of pigment composites

- The introduction of nanoparticle-based pigment structures
- Application of naturally occurring supports and colorants in the designing of novel type of functional pigments

The above is confirmed by the numerous R&D projects carried out at scientific centers and in industries, which to date have published more than 86,900 scientific papers related to inorganic pigments (Scopus database 10.01.2021), 69,400 – related to hybrid pigments and more than 205,000 – related to functional pigments.

The main reason for the high level of interest, particularly in the use of nanoparticles, is the possibility of improving the barrier properties of coatings, and thereby also corrosion resistance and mechanical properties. Other drivers of innovation in the field of pigments are environmental awareness, economic pressures, and the constantly changing needs of the industries, which consume these products. Hence the greatest level of development is observed in relation to pigments with special functionality such as anticancer, anti-inflammatory, and antioxidant properties, including hybrid pigments prepared utilizing naturally occurring colorants as well as supports (biopolymers). By using simple procedure of designing new dye-biopolymer pigments increases the possibilities of utilizing those materials and points out perspectives for their further development and practical use. All of these aspects ensure unceasing demand and continued efforts to obtain a wide color range of inorganic, hybrid, and multifunctional pigments, whose importance can be expected to continue to increase.

Tristimulus colorimeter

Definition

There are two kinds of modern colorimeters: one that includes and one that excludes a light source for measuring the surface or a self-luminous

stimulus respectively. Both types of colorimeter measure International Commission on Illumination (CIE) tristimulus values under particular illuminant and observer conditions, e.g., D50/2°. The instruments are applied to measure a test stimulus displayed on a monitor, printer or a light stimulus. CIE International Lighting Vocabulary [1] defines the colorimeter as an instrument for measuring colorimetric quantities, such as the tristimulus values of a color stimulus.

Overview

The colorimeter measures XYZ values in a luminance unit. This overview is divided into four sections: optical structure, measurement geometry, spectral responsivity and measuring uncertainty, and applications [1] (► [Photodetectors](#)).

Optical Structure

The structure of the colorimeter can be divided into two parts: the measuring head and the digital display. Figure 1 shows the schematic structure of a colorimeter. The measuring head contains tristimulus filters, detectors, and spatial corrections of the detector response. There are filters in front of the detectors to filter the input light, which is from the entrance window. The filters mimic the CIE color-matching functions. The parallel photodetectors sense the filtered light in the electronic signal ► [Photodetectors](#). The multiplex amplifier can integrally form the signal to feed via output channels. Finally, the XYZ tristimulus is reported on a digital display [2].

Measuring Geometry

There are three factors affecting the measurement results: the limiting aperture, the acceptance area, and the optical axis of the colorimeter head. The limiting aperture affects the quantity of the incoming light. The acceptance area evaluates the incident radiation to improve accuracy. The optical axis is the middle point of the measured surface or light source, which is related to the light entrance of the measuring head [3]. Figure 2 reveals 0°a/45° measuring geometry; more details are shown under (► [Photometer](#)).

Fig. 1 Schematic structure
of a colorimeter [3]

Instrument: Colorimeter, Fig. 2 0°a/45° measuring
geometry

**Spectral Responsivity and Measuring
Correction**

The measured spectrum is reported across a visible spectrum of 380–780 nm. Because the color-matching functions (CMF) $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ approximate the three human spectral responsivities, the real relative spectral responsivities (RSR) $s_{x,r}(\lambda)$, s_y ,

$s_z(\lambda)$, $s_{z,r}(\lambda)$ show some deviation. They do not match the color-matching functions exactly.

The mismatch correction of the spectrum must be considered; many of the corrected factors are used to evaluate the mismatch and to correct these deviations. For example, there are three types of factors corrected by comparing actual and target functions: the spectral mismatch, ultraviolet response ($f_{UV,i}$), and infrared response ($f_{IR,i}$). The corrected indexes are also used for the correction of the spectral transmittance factor ($\bar{\tau}(\lambda)$).

Applications

The colorimeter can measure XYZ tristimulus values in the illuminant industry, in paper reflectance, and in digital imaging. All of the measuring data, which calculate the color tristimulus to compare the test with reference values, following the CIE CMF, are employed, the user demand to determine the visual angle, and choose the corresponding CMF data (2°/10°) [2]. Moreover, the reference illuminant is also considered when the colorimeter calculates the XYZ tristimulus [4].

Most important for the colorimeter is that it is used to assist in calibrating color devices. For a printer, the colorimeter measures the different color patches that are printed on the paper. The measurement results are compared with the reference printer data, and the color difference is calculated to ensure colorimetric consistency.

Applications in the lighting industries can measure XYZ tristimulus in units of luminance (cd/m^2). The luminance can be represented clearly to correct the illuminant. Furthermore, the hand-held colorimeter can be conveniently used outdoors to measure the correlated color temperature (T_{cp}) and luminance.

Instrument: Photometer,
Fig. 1 Luminous intensity
measurement [2]

Definition

The photometer is an instrument which can be used to measure photometric quantities such as luminance, illuminance, etc. The parameters are derived from means of law of additives and CIE spectral luminous efficiency functions. The instruments usually transport the measured data either digitally or analogly to display on the screen. CIE had defined the international vocabulary of the photometer: instrument for measuring photometric quantities [1].

Overview

The photometer is a universal vocabulary which has plenty of types. According to the applications, the types can be divided to luminance meter, illuminance meter, etc. The luminous-intensity meter is a conventional photometer, which can measure directly luminous intensity (candela, cd). This article will focus on the luminous-intensity meter and is divided into three sections to introduce luminous-intensity meter structure and measuring theories, measuring fields and range, and applications and comparison [1–3].

Luminous-Intensity Meter Structure and Measuring Theories

The luminous-intensity meter consists mainly of detector unit. Following the measuring theories, the spectral weighting or the spectral dispersion device is arranged in front of the detector to separate the light. The lenses and apertures assist light transportation for luminous intensity measurement, see Fig. 1. The use of additional lenses can change the field of the focus to make it more

Instrument: Photometer,
Instrument: Photometer,
Fig. 2 The perfect
 conditions for luminous-
 intensity meter
 measurement [2]

flexible [4]. Luminous intensity can be ensured by measuring theories.

The data is measured by a detector which is included in the measuring detector that is transformed in terms of the digital signal, pass-through amplifier, and digital processes. If users must calculate other illuminant parameters such as luminance, illuminance, etc., the data can be outputted to the computer for further analysis.

Acceptance Area

Following the CIE definition, the acceptance area is the area of the luminous-intensity meter detector which is receiving and directionally evaluating the incident light. The acceptance area affects directly luminous intensity. In manufacturing processes of luminous-intensity meter, the measuring field must be defined accurately.

The measurement results are affected certainly by the environmental condition such as the background. The entire scene which includes light is also evaluated before the light input to the luminous-intensity meter detector. In the metrologically perfect conditions, the explanation is presented in Fig. 2. The light source is installed in front of the black background. The stray light is sheltered by baffles; the detector can receive the purer light that is not interfered with by the other nonstationary light [2].

Applications

The SI unit of luminous intensity is the candela (cd). The luminous-intensity meter can be used to measure light source in a particular direction per unit solid angle. The luminous-intensity meter is an adaptive tool to calibrate the optical

instruments. The sensitive detector is also applied to measure flicker or nonstationary optical wave. Furthermore, the other types of photometers such as luminance meter and illuminance meter can measure environmental variety. For example, luminance and illuminance are measured continuously for realizing LED light and overall light respectively. The correlation also can be found.

Synonyms

[Spectroreflectometer \(for reflectance measurement\)](#)

Definition

The spectrophotometer is an instrument for measuring the reflectance or transmittance quantities of an object, including specular and diffuse reflectance and regular and diffuse transmittance. On request, the instrument can measure the above quantities at different viewing/illumination geometry. The International Commission on Illumination (CIE) defines the spectrophotometer in its International Lighting Vocabulary [1] as an instrument for measuring the ratio of two values of a radiometric quantity at the same wavelength.

Overview

The spectrophotometer is used to measure spectral reflectance or transmittance across a visible spectrum. The structure consists mainly of a light source, a system of optical transmission, and a detector. Furthermore, the viewing geometries

also affect the measurement results. The instrument is composed of the following three parts: structure, viewing/illumination geometries, and application [1, 2].

Structure

The spectrophotometer consists of multiple structures to carry out light transmission and sample measurement. First of all, the measurement condition divides the wavelength into three sections: UV, visible, and IR sections. The deuterium lamp is used to measure the UV section. The visible and IR sections are measured by the halogen lamp. Second, the beam is divided into the reference beam and the sample beam. The reference beam and the sample beam are used to monitor stability and measure the sample, respectively. Finally, the two beams are transmitted by the multiple prisms and focused on the detector. The optical transmission is revealed in Fig. 1.

Instrument:
Spectrophotometer,
Fig. 1 The optical
transmission of a
spectrophotometer [3]

Instrument: Spectrophotometer, Fig. 2 Standard geometries for spectral reflectance [1]

Viewing/Illumination Geometries

The geometries for measuring reflectance depend on radiation field and angle; several standardized geometries are defined by the CIE. For color measurement, some of the standard geometries are shown in Fig. 2. The spectrophotometer commonly uses bidirectional geometry $0^\circ:45^\circ$ to calibrate the color in the National Measurement Laboratory R.O.C.

The Field of View

The tristimulus values are calculated from spectral reflectance, the factors are affected by the field of view ($2^\circ/10^\circ$). According to the CIE definition, the field of view can be decided by a range; if more than 4° , the field of view is 10° , and if less than 4° , the field of view is 2° . The field of view is one of the important elements for evaluating color. According to the field of view, the color-matching function (CMF) is divided into two types: the CIE 1931 2° Standard Observer and the CIE 1964 10° Standard Observer. The two types of CMF are used to fit the different measurement conditions.

Applications

For color measurement, the spectrophotometer measures a variety of surface colors, such as

textiles, coatings, and plastics. The results are reported as spectral reflectance or transmittance across the visible spectrum. The spectrophotometer is the appropriate device for measuring color data, and provides the correct color information for the manufacturing of textile products, printer products, and paint and material products to solve color difficulties.

Integrating Sphere

Cheng-Hsien Chen
Center for Measurement Standards,
Industrial Technology Research Institute,
Hsinchu, Taiwan

Synonyms

Ulbricht sphere

Definition

An integrating sphere is a hollow spherical cavity with a diffuse-reflecting material inside the sphere that has a spatially uniform surface, and a flat profile of spectral power distribution. The structure of integrating spheres generally consists of a baffle, different apertures, a light source, and a detector. The ideal integrating sphere has the following characteristics:

- (i) Small detector and external port.
- (ii) Miniature devices (light source, baffle, and mount) inside the sphere, which cannot affect optical radiation after its first reflection.
- (iii) The surface of the sphere is a homogeneous Lambertian reflector, with reflectance independent of the wavelength.

In color applications, an integrating sphere is used to produce a uniform light source from a luminaire or for measuring the transmittance or reflectance of a surface in a particular viewing geometry [1, 2].

Overview

As mentioned earlier, one application is for the measurement of the color properties of a

luminaire. In general, the substitution method is utilized to calculate the color properties of a test and a standard lamp, or transfer standard. The standard lamp provides the spectral flux, which can calculate the colorimetry and photometry quantities. Two types of detector are used on the sphere: a broadband $V(\lambda)$ -corrected photometer, and a narrow-band spectroradiometer [3]. The spectral mismatch error of the calibrated photometer should be corrected, according to the technical report of the International Commission of Illumination (CIE) [4]. The spectral response of the photometer is easy to apply to the measurement of the luminous flux of a test lamp. The spectroradiometer may be applied for spectral power distribution and colorimetry of test lamp measurement (Fig. 1).

When measuring surface properties, an integrating sphere is used as a uniform lighting source or a diffuser of the incident light. For the surface property measurement system, the integrating sphere is set to diffuse the reference beam and geometry structure to analyze the characteristics of the surface. According to various standard geometries, the integrating sphere provides various conditions to realize different optical properties (photometry, colorimetry, haze, gloss, clarity, shading, etc.) of the surface colorimetry and photometry measurement [5, 6].

The integrating sphere method requires a standard lamp, and the substitution method is often

Integrating Sphere,
Fig. 1 An image of an integrating sphere. The baffle inside the integrating sphere is designed to directly avoid the light incident on the detector port. The shadow from the baffle must cover the detector

utilized to calculate the total luminous flux of the test lamp. There are some important components inside the integrating sphere to consider. One such device is the baffle. The size of the baffle, used to prevent incident light from reaching the detector, depends upon both the size of the detector, and the distance between the lamp and the detector. A second device to consider is an auxiliary lamp. In practice, the shape of the test lamp is different from that of the standard lamp. The auxiliary lamp can provide the absorption correction function between the standard lamp and the test lamp.

The equation of luminous flux Φ_t is

$$\Phi_t = \frac{I_t}{I_s} \cdot \frac{A_s}{A_t} \cdot \Phi_s \quad (1)$$

where I_t is the signal of the test lamp, I_s is the signal of the standard lamp, A_s is the signal of the auxiliary lamp with the standard lamp, and A_t is the signal of the auxiliary lamp with the test lamp.

The photodetector shows some mismatches between the spectral luminous efficiency function and the spectral response of the detector and lamp source relation. The nonuniformity of the integrating sphere causes the directional light source to contribute measurement errors inside the sphere. The baffle size and different geometry inside the sphere provide varying spatial response distribution. Therefore, the equation of luminous flux Φ_t is given by

$$\Phi_t = \frac{I_t}{I_s} \cdot \frac{A_s}{A_t} \cdot ccf \cdot scf \cdot \Phi_s, \quad (2)$$

where ccf is the spectral mismatch correction factor, and scf is the spatial response distribution function (SRDF) of the integrating sphere [7, 8].

A good measurement system of an accreditation laboratory should have a suitable traceability chain. The metrological traceability chain, according to the International Standards Organization (ISO) guide 99 is the property of a measurement result whereby the result can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty. Therefore, the product

line quality control of manufacturing needs a transfer standard from the calibration laboratory. The calibration laboratory uses the reference standard trace to the National Measurement Institute (NMI), and then the trace to the SI unit shown in Fig. 2.

The stable and repeatable transfer standards, which have similar characteristics to the test lamp, are needed for the measurement system to transfer photometric and colorimetric units from the NMI or an accreditation laboratory. In practice, the transfer standard is made by a light-emitting diode (LED) lamp whose optical characteristics are similar to those of the test lamp and are measured using the same measurement instrument. For the calibration laboratory, the luminous flux measurement system transfers the standard from the reference standard to the LED transfer standard. The NMI transfers the standard, which is made by a stable, repeatable, and broadband spectrum lamp, such as a tungsten or halogen lamp, to the calibration laboratory.

For the luminous flux measurement of lighting, an integrating sphere is sometimes used together with calibration with a standard lamp that has similar characteristics and by using a comparison method to transfer luminous flux quantity to the measurement instrument. Measurement of LED lighting involves two kinds of measurement geometries. First, the test sample is mounted on the integrating sphere. Second, the test lamp is located in the center of the sphere. Why do the test lamp and standard lamp have similar characteristics? Because the measurement result is achieved by comparing the input and output signals. If we consider the spatial nonuniformity of integrating, by rotating a scanning beam, we will find the nonperfect output of the integrating sphere. If we use the narrow beam light source to scan inside the sphere, we measure the different signal from the detector in the different scanning region shown in Fig. 3.

The 2π geometry would have two zones, and zone 2 would have a drift signal as the large scanning beam angle. This means that when using a wide diverging angle lamp such as a halogen lamp or a diffused lamp such as a standard lamp, and the narrow diverging angle of the

Integrating Sphere, Fig. 2 The metrological traceability chain of a luminous flux standard lamp calibration system

test lamp such as some 5-mm LEDs, there would be more measurement uncertainty for calibration, because the large size of the integrating sphere and perfect Lambertian surface were good for measuring the luminous flux of the LED. For the 4π geometry, zone 1 is the baffle region with the scanning beam near the edge of the baffle, and we would measure a higher signal from the detector. Some light is directly incident to the detector because of scattering. If we use a large sphere and a baffle and mount of smaller geometry, a large area of the flat region would be zone 2. Zone 3 is the shadow region made from the baffle and detector by the scanning beam.

Most important is the light distribution between the standard lamp and the test lamp. If the light distribution is different, the spatial non-uniformity of the integrating sphere should be considered. The nonuniformity of the integrating sphere causes the directional light source to make a measurement error inside the sphere. The

baffle size and different geometry inside the sphere provide a different spatial response distribution.

Ideally, the light distribution of the device under test (DUT) lamp and the standard lamp should be similar. If not, the spatial distribution mismatch correction is applied complexly. If measurement of a directional light source is required, for which the light distribution is different from the standard lamp, the spatial response distribution function (SRDF) should be considered. The SRDF is relative to the baffle size, the DUT lamp, and the geometry inside the sphere. In practice, the point source in the center of the sphere should be used and the light distribution of the DUT measured to calculate the SRDF. In addition, the same method of evaluating the SRDF to measure the directional light source in the center of the integrating sphere can be used. Overall, by knowing the limitation of the integrating sphere, the directional light source can be precisely

Integrating Sphere, Fig. 3 Spatial nonuniformity of the integrating sphere

measured, and the measurement uncertainty can be reduced [9].

Synonyms

Color and light effects; Color and light interdependence; Influences between light and color

Definition

Color cannot be observed without light, and without material artifacts light is not visible – thus, one can simplify and say: no color exists without light and no light could be present without color. Color is a visual sensation that depends, among other factors, on stimulation of the visual system by radiation within the visible range – light – either emitted by a source or transmitted or reflected by *pigmented* objects. Indefectibly, light has color; there is no colorless light (light can be white, but white is also a color sensation). The chromatic composition of incident light affects the perceived color of pigmented surfaces. Color and light are like both sides of the same coin; they cannot be separated. For the creative disciplines involving design (design, *interior design*, *scenography*, architecture, etc.), the use of color and light and the knowledge about how one interacts and influences each other is a fundamental issue.

Interactions of Color and Light in the Context of Creative Training and Practices

Initial Position

In creative training and practices, the determining aspects of the interactions of color and light are

generally not represented in a systematized manner. The present authors have responded to this shortcoming in collaboration with Florian Bachmann, Marcus Pericin [1], and others by examining the relevance of the interaction of color and light and by describing the aspects of it which are most important to creative training and practices. In addition, they use different approaches to exemplify the makings of a new teaching model.

Color cannot be observed without light, and without material artifacts light is not visible. Thus, one can simplify and say: no color without light and no light without color. For the creative disciplines, the use of color is one of the fundamental dimensions. And yet, despite the reciprocal interdependence of color and light, there has as yet been no comprehensive and systematizing concept for theory and creative practice.

Research on the Interactions of Color and Light in the Creative Disciplines

This entry is based on three research projects on the interactions of color and light which build upon each other's findings: ColorLightLab, LED-ColorLab, and Colour and Light – Materials for a Theory of Colour and Light [2].

The research starts from the premise that design systems using color and light which are employed in design practice (and by analogy in *interior design*, *lighting design*, etc., as well) do not relate to each other. This despite the fact that material color cannot be perceived without light and that light cannot be seen in the absence of material artifacts. This shortcoming is reflected in the practice and methods of creative teaching. There is no theory which combines color and light in a systematic manner. The aim of the research was to pursue a practically oriented investigation of the principles involved in the interaction of color and light in terms of the requirements imposed by design and, in addition, to express research findings in practically relevant materials towards a color-light theory.

ColorLightLab

This project investigated the principles of the interactions of light and material color. The research was carried out using the methods of artistic research and research through design [3–5] and culminated in a presentation of the phenomena under investigation and the publication *Colours Between Light and Darkness* [6].

LED-ColorLab

The focus was on an investigation of the interaction of dynamic light and colored surfaces in a spatial context. Here the interactions of dynamic light in the color spectrum were systematically observed, as were those in the spectrum of white light. The findings were presented in a laboratory display and evaluated in surveys with experts (architects, *interior designers*, designers, *lighting designers*, etc.) and with consumers. Approaches from the realm of research through design were combined with survey methods.

Colour and Light – Materials for a Theory of Colour and Light

Here the focus was on conveying the practical relevance of the previous findings. Materials for a theory of color and light (installations, digital and physical tools) were developed in an experimental context and evaluated by experts as well as school and university students (methods used were research through design as well as qualitative and quantitative surveys). These materials were summarized in a multimedia publication [7] which comprises: description of the installations, contextualization of practice, theory and research, compendium of a DVD with videos about the installations, a specifically developed software, and a relaunched website setting attitudes to the interaction of color and light in the context of historical systems of color.

The experiments and empirical investigations were set up on the basis of the following research questions:

- How is the *perception of color* on surfaces and in spaces affected by lighting?

- What effect does the physical composition of surfaces, materials, and spaces have on the perception of color under different lighting?
- What interactions occur between dynamic light and colored surfaces?
- How can one arrive at a comprehensible description of the interaction of dynamic light and colored surfaces?
- What are the requirements to be met by materials and instruments used in a theory of color and light?

These questions derive from experiences gained in design practice and theory.

Summary of Investigations

First, models and prototypes were built, and several test measurements were carried out to compare the differentiation of various surfaces and various light sources; then a measuring system was constructed, where calibrated light falls on two precisely defined and identical surfaces in such a way that the remitting light can be measured by means of sensors. Thus, a kind of color-sampling booth (*LED-ColorCase*) was produced, enabling surface colors under different light sources to be visually compared and methodologically described. The *LED-ColorCase* makes it possible to record and evaluate *hue* shifts visually and in terms of spectral analysis. What is striking is the powerful influence of the light sources used on the difference of the resultant color effects. It was also possible to verify the possibility of calculating and predicting the resultant color impressions.

The experiments and laboratory investigations in the *LED-ColorLab* project showed that hue shifts develop a far greater differential under different light sources than was previously supposed and that they are clearly perceptible. In general terms one can say that the effect of and alteration caused by *hue*, *saturation*, and *brightness* is underestimated and generally not sufficiently taken into account in color and light design. In an ideal situation, it should be possible to give such alterations primacy during planning and to move towards predicting them.

Summary of Surveys and Empirical Aspect

The empirical aspect of the *LED-ColorLab* research project resulted in clear findings in terms of practical applicability. Surveys carried out during the LED – Staging Color and Light [8] exhibition (a public laboratory situation and part of the *LED-ColorLab* research project) showed that one can recognize the importance of the interactions of dynamic light (across the whole color spectrum but also dynamically in the white light spectrum from cool white to warm white): experts in the fields of architecture, *interior design*, design, and *lighting design* rate this potential highly in terms of their own creative practice. At the same time, the experts who were questioned demonstrated a lack of methodological and technical knowledge. End users questioned in the *LED-ColorLab* installations

use recent lighting technology either as mood lighting or task lighting (this relates to *LED*). They rate highly the potential for integrated use of color and light in their personal environment and their place of work. Regarding the effects of the color shifts described above, acceptance is almost at 90% overall.

Similar results are seen in analysis of the responses to the research project *Colour and Light – Materials for a Theory of Colour and Light*, which took as its focus the development and evaluation. In the course of in-depth interviews and on the basis of surveys in the display of materials, 71% of the experts questioned acknowledged not only the quality of the materials produced but also the underlying approach towards a theory of color and light for creative practice.

Interactions of Color and Light, Fig. 1 Color-light keyboard installation; project: staging *LED-Color*. It is a 25-m-long spatial installation, which consists of 15 large-scale wall panels painted on one side in the same gray and on the other with different, highly pigmented monochrome colors: white, gray, green, red, ultramarine, and black. The surfaces are illuminated with changing colored LED

lighting according to an animated score of color and light. Because the installation can be entered on foot, the dynamic interactions of color and light can be directly experienced in a spatial context. In this way the installation points towards the great scenic and dramaturgical potential of such compositions of color and light for design and the performing arts

Implementing Knowledge as Mediation Tools and Materials

The principles of interactions of dynamic light and colored surface were laid out in the multimedia publication *Colour and Light: Materials for a Theory of Colour and Light* [7]. Here the aspect of direct sensual perception is given especial prominence. The authors are convinced that a theory of light and color has a particularly strong influence on creative practice if it exploits direct sensual perception of the phenomena of the interactions of color and light. In this the authors are following, among other influences, the concept of the German philosopher Gernot Böhme who writes, using the argument of an aesthetic (a general theory of perception) about the effects of atmospheres: “the primary subject of sensual perception is not the things one perceives but what one feels: atmospheres” [9]. As a consequence, conclusions drawn from the creative

experiments as well as experience gained from the installations and tools were used to develop elements of a didactic concept in which sensual perception of the phenomena of the interactions of color and light are linked to the direct experience of learners.

Selected Instruments of a Theory of Color and Light

Installations

The authors identify as installations such arrangements as permit different perceptual phenomena relating to color and light to be placed in a spatial context so that they can be experienced by the senses. They evolve from observations such as can also be made in everyday life. In contrast, the phenomena thus presented are detached from the context of their surroundings and then staged

Interactions of Color and Light, Fig. 2 Color-light playground tool; project: *Colour and Light – Materials for a Theory of Colour and Light*. This tool stimulates experimentation with dynamically controlled LEDs and color-coated angled sheet metal which can be assembled

in a variety of combinations of color and space. Hue, saturation, and brightness can be altered manually, enabling active experience of the interactions between surface colors and colored light

Interactions of Color and Light, Fig. 3 The color-light toy

and varied spatially, such that these aspects, or some of them, can be perceived in isolation from it. In this process *hue*, *saturation*, and *brightness* of the colors observed are affected to varying degrees (Fig. 1).

Tools

The term “tools” refers to materials which facilitate play-based and experimental access to various perceptual phenomena around light and color. These include physical as well as digital tools. They encourage independent or directed experimentation and thus facilitate the acquisition of experiential knowledge in individualized learning processes (Fig. 2).

Color-Light Toy

The color-light toy is a virtual 3D environment where complex interactions of surface colors and light and various contrast effects can be simulated interactively (Fig. 3).

Conclusion

The authors’ research demonstrates the lack of integrative principles and practices in the field of designing using color and light, especially in the context of architecture, *interior architecture*, design, and *scenography*. The research demonstrates the high degree of willingness to apply the phenomena of interaction of color and light professionally and as end users. The approach of implementing the abovementioned phenomena into a mediation concept which can be experienced and experimented on, and which is focused on aspects of direct and sensual perception, is

being further developed by researchers into color and light at various institutions [10].

Definition

Lighting concepts for interior spaces can be found everywhere, be it the concept to allow daylight to penetrate in a building without causing glare or overheating, be it the concept to create appropriate lighting conditions in offices, or be it the specifics of museum lighting to highlight art without damaging it by radiation or heat. Interior lighting is about choosing the appropriate lighting components in a lighting design to fit the requirements of a certain application (examples in Fig. 1).

Germany

Synonyms

Indoor lighting; Lighting for indoor spaces; Lighting for interior spaces

Overview

Interior lighting can be applied to:

- Support safety from a visual point of view
- Provide adequate lighting conditions for activities in terms of quantity and quality
- Enhance the desired room appearance/lit environment
- Create an atmosphere suitable for the space that is lit

Interior Lighting, Fig. 1 Examples of interior lighting. (All pictures: Philips Lighting)

- Enhance health and well-being
- Support an architectural design

The first five aspects are related to the individuals (individual well-being) using the space; the last aspect is related to the space itself. Lighting for safety and lighting for performing activities need to be considered as minimum lighting conditions. This so-called functional lighting is typically referred to in standards, whereas aesthetic lighting, clearly related to atmosphere creation and support of architectural designs, is less specified. Depending on the application, these aspects will vary in their emphasis. For example, atmosphere creation is of higher importance in restaurants and shops; enhancing well-being with lighting is typically taken into consideration in lighting designs for, e.g., schools, hospitals, or office buildings.

Safety needs in normal operation, for example, to safeguard not to stumble over obstacles in a corridor or to safely operate industrial machines, are usually fulfilled when lighting conditions to perform activities in the space are realized. Safety in temporary, untypical situations, mainly in case of electrical power loss, needs to be addressed as well. In this case, the lighting needs to guarantee that the building can be vacated safely without electrical energy in a given time frame. Requirements for the so-called emergency lighting can be found in, for example, EN 1838:2013 Lighting applications – Emergency lighting and CIE S 020/E:2007 Emergency Lighting [1, 2].

Lighting to realize adequate conditions for activities focuses on the lighting needs for visual performance and visual comfort. Aspects to be considered are, for example, protection from glare caused by either daylight or electric lighting in office rooms, minimum lighting levels to perform visual tasks in almost all applications, color rendering requirements to enable differentiation between colors, which is specifically important, for instance, for color inspection, and in a large number of areas in health-care premises.

Lighting can be applied to enhance room appearance. Several studies indicate that people prefer relatively bright vertical surfaces [3–5].

Research [6] has indicated that the appearance of a space is related to the lighting characteristics of a 40° band of view for an observer (20° above and 20° below the line of sight). The luminance of this band has a large effect on the perception of dim-bright and uniform-nonuniform. A room is perceived bright from an average luminance of 30–40 cd/m² [6, 7, 8]. Additionally, the average scene luminance and ceiling luminance are also relevant parameters in the satisfaction rating of a lighting system [9].

Lighting to create an atmosphere sets the right scene for the purpose of the interior space. In retail and hospitality applications, lighting is an influential parameter to create an inviting space, to stimulate communication or to attract shoppers. Research has been conducted in the 1970s [10] and more recently [6, 11, 12, 13]. It indicates, for example, that to realize an intimate atmosphere, diffuse warm lighting should be applied; a businesslike, neutral atmosphere is created with diffuse cold lighting. Visual clarity is achieved with high workplane and wall luminances. A place works confined, narrowing when direct overhead lighting is applied at low lighting, without illuminating the walls. Nonuniform, moderate light levels and nonuniform wall lighting induce pleasantness.

Light is important to people's health and well-being. It can affect people's physiological and psychological state. Although already researched in the 1980s and 1990s, it received a broader interest after the discovery of a new photoreceptor (ipRGC) in the retina of the eye [14]. When light reaches these cells, signals are sent to the central biological clock (suprachiasmatic nuclei – SCN), which regulates circadian and circannual rhythms of a large variety of bodily processes. This influences, for example, sleepiness and alertness. The lighting community is still exploring how light can be used to support the healing process in hospitals, to improve learning conditions for pupils in schools, or to improve shift workers' sleep quality during the day and alertness during the night. Current research indicates that higher illuminances and a wider range of color temperatures than typically specified in standards can stimulate people and enhance their well-being

(► [Non-visual Lighting Effects and Their Impact on Health and Well-Being](#)).

Lighting can also be used to support the architectural design, by using coves and large lit surfaces to define the space, as well as by highlighting architectural details, such as columns, arches, and galleries (► [Architectural Lighting](#)).

Lighting Quality

Although no precise definition for lighting quality exists [15], lighting quality is typically related to the degree of which the lighting conditions meet needs of users of the space. A large field investigation in office buildings [9] has indicated that the effect of lighting that is perceived of higher quality can be considerable. The study shows that, through environmental satisfaction, lighting quality can affect job satisfaction, organizational commitment, and turnover, as well as health problems and self-assessed performance.

In order to realize good quality lighting, the lighting solution needs to fulfill the requirements set by/coming from the various target groups, for example, the user, the owner, and/or the designer. The quality of the lighting solution is determined by the fulfillment of the set lighting purpose(s) (see before) as well as the economic, environmental, and design aspects of the solution, such as style, integration into architecture, appropriateness of appearance, form, and size (from [5, 16]). Quality lighting can be achieved by the right choice of lighting components (light sources, luminaires, and lighting control) in an appropriate lighting design.

This part on interior lighting will focus on quality aspects of lighting conditions for activities, as mentioned above. Typically, requirements for this lighting can be found in standards and recommendations (e.g., [15, 17–20]), which ensure that the user in the application is able to comfortably perform basic visual work. The following aspects are usually seen as minimum considerations.

Task Visibility

In order to have appropriate task visibility in indoor spaces, a minimum required (average) illuminance level is given in standards and recommendations. Just as an example, in the European standard EN 12464-1 [18], a minimum average illuminance of 500 lx is given for writing, typing, reading, and data processing in office buildings; color inspection in chemical, plastics, and rubber industry requires 1,000 lx. A minimum uniformity of illumination ($E_{\min}/E_{\text{av}}$) is demanded to prevent frequent reaccommodation of the eyes. In the European Standard the required uniformity lays between 0.4 (for an easy task or in the surrounding area of a task) and 0.7 (difficult task).

In order to prevent errors, fatigue, or accidents, one should ensure that reflections in specular surfaces (veiling reflections) are not present. These reflections, which partially or totally obscure the details to be seen by reducing the contrast, will diminish task visibility. Maximum average luminance values are given to avoid reflected glare on computer screens [18]. When it comes to reflections in glossy material (e.g., magazine) or glass (e.g., vitrine or pictures) (see Fig. 2), design rules that define the appropriate position of the light sources (outside the so-called offending zone)

Interior Lighting, Fig. 2 Examples of veiling reflections

can be applied to prevent veiling reflections (see, e.g., [21]).

Visual Comfort

When too high luminance differences are offered within the field of view, glare can be caused. Discomfort glare is the type of glare that does not directly reduce the ability to see an object, but it produces a sensation of discomfort and might affect performance in the longer run. Glare which impairs vision is called disability glare. In indoor lighting it is assumed that disability glare does not occur, when both shielding angles for bright light sources and discomfort glare restrictions are applied. The degree of discomfort glare can be assessed with the Unified Glare Rating or Visual Comfort Probability. Standards and recommendations provide maximum (UGR) and minimum (VCP) values to ensure comfortable lighting conditions in a specific application. For example, for offices the required UGR is typically 19, the recommended VCP value is 70. For situations with VDT tasks, a VCP value of 80 is recommended (► [Glare](#)).

Whereas the task visibility and visual comfort aspects are related to the lighting solution in a specific application, standards and recommendations refer to minimum requirements for characteristics of light sources as well. Both flicker and color rendering are qualities to be assessed, as they might hamper visual performance when requirements are not met.

Visible, but also invisible, flicker can trigger headaches, fatigue, and distraction. It has been shown to reduce performance. If it results in stroboscopic effects and objects appear to move discretely rather than continuously, it can lead to critical situations, e.g., in industry when interacting with rotating or reciprocating machinery. The Critical Flicker Frequency and the Flicker Index are used in the past to assess flicker, but research indicates that not all relevant parameters are covered in both measures [22–24]. New metrics are looked into, to be used to predict both flicker and stroboscopic effects for all light sources, including LED (e.g., [25–28]).

For visual performance, colors in the environment shall be rendered naturally and correctly.

The general color rendering index (R_a) of a light source is used as an indication of how well this light source reproduces colors of an object in comparison with a reference (ideal or natural) light source. The maximum value of R_a is 100, and the required value is depending on the application. For example, according to the European Standard EN 12464-1 [18], indoor circulation areas require a minimum R_a of 40, offices a value above 80, and areas for fabric control in textile manufacturing or examination and treatment rooms a minimum R_a of 90. The color rendering index of a light source can be obtained from the manufacturer, the package, or the lamp itself (► [CIE Color-Rendering Index](#)). The R_a has limitations, especially for LED light sources, and other metrics to describe color quality are developed for practical application (e.g., in [29]) and usage in research [30].

A number of quality measures go beyond task performance. Generally, these are listed in standards or recommendations as well, with proposed minimum levels to achieve a higher lighting quality, to benefit human health and well-being (e.g., in [18, 20]). Examples are:

- Color appearance, which is referring to the color of the light, quantified by its correlated color temperature (T_{CP}). For electric lighting, it ranges typically from 2,700 K (warm white light) to 6,500 K (cool white light), with a maximum of 17,000 K. The choice for a certain color appearance depends on the application, the atmosphere to be created, the colors of furniture and room partitions, the illuminance level, climate, and culture.
- Modelling of faces for visual communication and recognition of faces. In order to achieve this, the lighting in a room should not be too directional nor too diffuse. Design guidelines propose to use as little as 20% of the total illuminance from a diffuse or reflected light source and avoid strongly directional lighting (e.g., [19, 20, 31]).

It needs to be noted that the abovementioned quality criteria typically focus on minimum requirements to assure visual performance and

visual comfort. As indicated before, room appearance is of great importance for the user's well-being. The standards, mainly focusing on minimum requirements for task illumination, will not sufficiently address this. Although minimum required vertical illuminance is mentioned in the IES Handbook [16] and the EN 124641:2011 [18], the needed lighting levels for quality lighting addressing also room appearance and people's health and well-being are likely higher.

Interior Lighting Design

Interior lighting is about choosing the lighting components in a lighting design to fit the requirements of a certain application.

As indicated before, a lighting design consists of functional lighting and/or aesthetic lighting. Typical application areas with a focus on functional lighting are industry (e.g., assembly work, storage) and office (e.g., open plan office, cell office, meeting room, corridors). Typical application areas with additional aesthetic lighting are retail (e.g., department stores, boutiques), hotels (e.g., entrance areas, reception areas), and restaurants.

Resulting, interior lighting is often built up from layers of light. Depending on the application, one or more layers are applied, typically distinguishing between

- **General lighting:** lighting providing (horizontal) illumination over the total area of the room with a certain degree of uniformity. General lighting is often offered in a regular grid of point, line, or area light sources (see Fig. 3) (► [“Coefficient of Utilization, Lumen Method,”](#) ► [“Diffuse Lighting”](#)).
- **Task lighting:** additional lighting to general lighting in the area in which the task will be performed. Task lighting is used to fulfill the requirements, without having to illuminate the entire room to that specific level, in order to reduce energy consumption for electric lighting (see Fig. 4) (Task Lighting).
- **Accent lighting:** directional lighting to emphasize a particular object or to draw attention to a part of the field of view (see Fig. 5).
- **Decorative lighting:** the lighting itself provides a point of interest or attraction in an interior (see Fig. 6).
- **Architectural lighting:** lighting to form or underline the architecture of the space (see Fig. 7) (► [Architectural Lighting](#)).

All layers have specific requirements, which the lighting components have to fulfill.

Lighting Components for Interior Lighting

Lighting for indoor places can be provided by daylight, electric lighting, or a combination of both. In this entry, only electric lighting is discussed. As interior lighting is about choosing the lighting components in a lighting design to fit the requirements of a certain application, the lighting components will be briefly discussed below.

Interior lighting is used in a wide spread of applications with a wide range of requirements. Resulting, a large variety of light sources and luminaire types are applied in interior lighting. The most relevant characteristics that determine the applicability of a light source in a certain application are luminous flux, efficacy, luminance, color rendering, correlated color temperature, lifetime, run-up time, reignition time, and form factor of the light source. In the design process the application requirements on these aspects need to be specified, in order to select the appropriate light source.

To give an impression, without being conclusive, one can roughly say that halogen lamps are generally applied in aesthetic lighting, in accent lighting, and in decorative lighting (► [Incandescent Lamp](#)). Fluorescent lamps can be found in applications with a focus on functional lighting, in both general lighting and task lighting, such as industry, health care, educational buildings, and office. Next to that fluorescent lamps are used in architectural lighting solutions,

Interior Lighting, Fig. 3 Examples for general lighting: point (two pictures on the top), line, and area light sources. (First picture: Philips Lighting)

such as coves and luminous ceilings (► [Tubular and Compact Fluorescent Lamp](#)). High-intensity discharge lamps (e.g., ► [Metal Halide Lamp](#)) can be found in general lighting solutions as well as accent lighting solutions, in, for example, industry and retail applications. LEDs have been successfully introduced in interior lighting as well and can be found in both functional and aesthetic lighting solutions. The diversity of LEDs allows for usage of this light source in general, task, accent, decorative, as well as architectural lighting (► [Light-Emitting Diode, LED](#)).

With respect to the luminaires (► [Luminaires](#)), a similar specification of requirement needs to be made. Based on the chosen required lighting concept (functional and aesthetic, from general lighting to architectural lighting), the following

characteristics of the luminaire can support luminaire selection: the light distribution (luminous intensity distribution – ► [“Light Distribution”](#)), efficiency (reflected in light output ratio), IP class, form factor, and type (recessed, surface mounted, suspended, wall mounted, free floor standing, or desk luminaire). The variety is large, serving the broad bandwidth of requirements in interior lighting.

In the overall lighting design, lighting controls need to be considered. Reasons to use lighting controls in interior lighting are to:

- Make use of potential energy savings, such as time control, occupancy control, and controls that respond to the daylight availability in the room (daylight supply control)

Interior Lighting, Fig. 4 Examples for task lighting. (All pictures: Philips Lighting)

- Increase user comfort and well-being, such as personal control, glare control, and controls that offer lighting settings for specific tasks (task demand control)
- Support building appearance, ambience, and company representation, for example, using scene setting

Lighting controls can enhance the quality of a lighting installation. Once more, the specification will depend on the application. The use of occupancy control is, for example, suitable in areas where people generally stay a relatively short period or do not feel responsible for switching

off the lighting, such as bathrooms, stair cases, and warehouse aisle. Daylight supply control is applied in situations with sufficient daylight and an appropriate choice, for example, in open plan offices and hospital wards (► [Lighting Controls](#)).

The combination of components – light source, luminaire, and controls – will determine the overall quality of the lighting.

Concluding

Interior lighting serves a number of objectives. Each application requires a specific approach,

Interior Lighting, Fig. 5 Example for accent lighting. (Picture: Philips Lighting)

Interior Lighting, Fig. 6 Examples for decorative lighting. (Second picture, Philips Lighting; photo credits, Cinimod Studio – third picture, Philips Lighting; photographer, Leon Verlaek)

typically build up from a few layers of light, fulfilling demands of the user of the space and its architecture. Good quality lighting respects

these demands, as well as the economic, environmental, and design aspects. A combination of suitable light sources, luminaires, and lighting

Interior Lighting, Fig. 7 Examples for architectural lighting. (Second and third picture: Philips Lighting)

controls in an appropriate design will offer good quality lighting in interior spaces.

Internet of Things and LEDs

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,

IoT

Definition

IoT is a network that connects uniquely identifiable “things” to the Internet. The “things” have sensing/actuation and potential programmability capabilities. Through the exploitation of unique

identification and sensing, information about the “thing” can be collected, and the state of the “thing” can be changed from anywhere, anytime, by anything [1]. LED lighting systems can be used both as the network for IoT systems and as the carrier for the required sensors and activators.

Internet of Things (IoT)

In more laymen terms, the definition of Internet of things can be described as a system that:

- connects us with physical devices (“things”) around us,
- collects and stores information (data) from these devices,
- smartly controls the devices around us based on the collected information.

A typical example of an IoT system is the self-driving communicative car. With this system, my

car communicates with other cars, collects information from them (including steering and braking actions), analyzes the collected data, and decides how to react and executes the best maneuver.

IoT needs four fundamental components:

- Sensors (getting data)
- Activators (executing commandos)
- Network connection
- Data processing (analyzing)

Figure 1 shows the relationship between the Internet and the Internet of things (IoT). Internet connects me with other persons (you) and with our PC, tablet, and smartphone. In different environments, such as our home, offices, factories, shops, roads, and hospitals, many IoT-enabled devices which incorporate sensors and activators are interconnected in local networks, which, in turn, can be connected to the Internet. Some sensors may be located on ourselves. Think of smartwatches which sense heartbeat, activity,

Internet of Things and LEDs, Fig. 1 Internet and Internet of things (IoT) connections

and many other things. Perhaps sounding futuristic, some persons will have chipped sensors which directly connect with their medical professionals. As an example, for the office environment, two different networks, connected with the Internet, are drawn. These could, for instance, represent a lighting network with integrated sensors and activators and an HVAC network with integrated activators.

Microcontrollers, activators (e.g., for switching and dimming), and sensors, such as light, occupancy, temperature, humidity, and noise sensors, are small enough to be incorporated in the LED luminaire from which they also get the power needed for their operation. The sensors used in the smart lighting network can be expanded with sensors that collect information, such as occupancy, temperature, humidity, and air quality needed to control and optimize other installations in the building. The smart lighting network so becomes the “heart” of the Internet of things of that building. An IoT lighting system can considerably increase the energy efficiency of the electric installations in a building and reduce the costs of operating that building while ensuring optimized performance, comfort, and health of the building users.

IoT Lighting System

Infrastructure for IoT Lighting Systems

Crucial in IoT systems are the sensors that collect information from the things around us. IoT systems need a granular sensory network permitting sensors to be ubiquitous (omnipresent) and densely spaced and give them access to power. Such a network can “sense what is going on” at each spot of the space. Fortunately, there is no need for a new infrastructure for such a sensory network, as the lighting network fulfils the above requirements. The network of light points can serve as the infrastructure for IoT systems. This is not only the case for indoor lighting in the context of smart buildings but also for road lighting in the context of smart cities (Fig. 2). By having the sensors, or most of the sensors, integrated with the luminaires

themselves, the lighting system becomes an IoT lighting system.

IoT Lighting System Technology

Data received from the sensors can be stored and processed in the cloud. Local storing and processing of some of the data can be advantageous to get actions, as a result of sensed changes, fast enough for security reasons and to avoid failures of the system in case of bad network connections. The local storing and processing at the borders (edges) of the own network is in the IoT world referred to as “edge computing.” Usually, a combination of cloud and edge storing and computing is used in modern IoT systems. The quality of the analysis of the large amount of data received determines the effectiveness of the resulting actions of the IoT system. Machine learning, a field of artificial intelligence (AI) that uses complex statistics with which computer systems “learn” to improve their effectiveness continuously, offers important possibilities in this respect.

Incompatibility of connected devices of different manufacturers and the use of different, propriety or non-propriety, communication standards is a problem for interoperability. The European Union has therefore initiated the project OpenAIS (Open Architectures for Intelligent Solid-State Lighting Systems). It has defined an interoperability standard allowing different systems to work collaboratively [2, 3]. The project has been carried out by the OpenAIS consortium, existing of representatives of the European lighting industry and two academic institutions [4]. The consortium develops components and standards to connect all luminaires to the Internet. Technological advances and changes in working habits and regulations all play a role in the work of the consortium.

Services of IoT Lighting Systems

The data collected by the IoT system are available in real time as input for direct, smart actions of the connected building service installations such as lighting, heating, ventilation, and air conditioning (HVAC). Since the data are stored, they are also

Internet of Things and LEDs, Fig. 2 The network of light points, in buildings and on roads, is a granular network that is ubiquitous and densely spaced and has access to power and can, therefore, serve as the infrastructure for IoT systems

available for data-driven decisions by facility management such as space allocation, cleaning, and maintenance actions and for helping with diagnostics. Part of these decisions can be automated. For general management, the data can be used for the optimization of energy consumption and costs.

By following in real time the occupation of spaces suitable for different activities, new areas

can be made automatically available when needed. The not-needed spaces need no lighting and less heating and air conditioning. By having the system analyze the historical occupation data, individual rooms may be closed, again automatically, certain days of the week with all services completely switched off. The cleaning and maintenance schedule can be adapted to the actual occupancy situation.

Security management can be facilitated by automatic identification of persons with the aid of smart beacons installed at suitable places, including the entrances. These beacons communicate through Bluetooth with an app on the smartphones of the persons having access to a building. The same system can be used to locate a person or persons in an emergency and send short messages. Again the same method can be used to “tell” the luminaires and HVAC system which person is in the influencing area of them. In this way, the person, wherever he is in the building, can control the services of light, heating, or air conditioning around him with his personal control device, for example, his smartphone. Or, even more advanced, the services automatically sense the personal preferences of the person and switch the services accordingly. If desired, the system can be made to include the coffee or tea machine serving automatically coffee or tea according to the personal taste.

Customer relation management (CRM) by shops owners can benefit from IoT systems as well. By installing beacons in the shop and providing an app for customers, shoppers can be monitored as far as locations visited are concerned. This information can be compared with the CRM base, which, of course, includes what products are bought previously by the customer. Special offers can be custom-made, right on the spot. The next section discusses that such a shop app can also use the smart luminaires as the basis for an indoor navigation system so that the customer can easily find the products he is looking for.

Many IoT lighting systems realized in smart commercial buildings, using different kinds of data, are described in the literature.

IoT systems using the road lighting network as the carrier may become the backbone of smart cities. Sensors, built into the road lighting luminaires, can be used to control the road lighting itself, for example, in dependence of traffic speed and density, daylight availability, rain, fog, and frozen roads. Since information on the status of the LED light sources itself can also be made available, road lighting maintenance can be optimized. And, the same system can also be used to optimize the mobility in cities (and on motorways) by smart traffic and parking guidance

based on the information received from the sensors at different locations. Finally, the quality of life can be monitored and controlled to some extent. Think here of security, crowd control, and air quality control.

Under the entry “Visible Light Communication,” it is shown that LED light itself can be used as a sensor: LED lighting beyond illumination alone.

Interpolation of Spectral Data

Stephen Westland
Colour Science and Technology, University of
Leeds, Leeds, UK

Synonyms

[Subsampling](#)

Definition

Spectral data can be interpolated using Sprague interpolation when the original data are evenly spaced. This involves fitting a fifth-order polynomial between two points P_i and P_{i+1} thus:

$$f(x) = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 \quad (1)$$

which can be used to interpolate between the points P_i and P_{i+1} and where x is the proportional distance between P_i and P_{i+1} of the point to be evaluated. However, the polynomial is constrained so that the gradients and curvature are consistent with the points P_{i-2} , P_{i-1} and P_{i+2} , P_{i+3} (the two points either side of the points that are being interpolated between). This constraint results in the coefficients of equation being easily calculated from the points P_{i-2} – P_{i+3} [1] thus:

$$\begin{aligned} a_0 &= P_i \\ a_1 &= (2P_{i-2} - 16P_{i-1} + 16P_{i+1} - 2P_{i+2})/24 \\ a_2 &= (-P_{i-2} - 16P_{i-1} - 30P_i + 16P_{i+1} - P_{i+2})/24 \\ a_3 &= (-9P_{i-2} + 39P_{i-1} + 70P_i + 66P_{i+1} \\ &\quad - 33P_{i+2} + 7P_{i+3})/24 \\ a_4 &= (13P_{i-2} - 64P_{i-1} + 126P_i - 124P_{i+1} \\ &\quad + 61P_{i+2} - 12P_{i+3})/24 \\ a_5 &= (-5P_{i-2} + 25P_{i-1} - 50P_i + 50P_{i+1} \\ &\quad - 25P_{i+2} + 5P_{i+3})/24 \end{aligned} \quad (2)$$

However, for N points P_i where $i = 1:N$ the method cannot be directly used to interpolate between P_1 and P_2 nor between P_{N-1} and P_N because the additional points on either side do not exist. The CIE recommends a method for extrapolating four additional points, two at shorter wavelength intervals than available (P_{-1} and P_0) and two at longer wavelength intervals than available (P_{N+1} and P_{N+2}) thus:

$$\begin{aligned} P_0 &= (884P_1 - 1960P_2 + 3033P_3 - 2648P_4 \\ &\quad + 1080P_5 - 180P_6)/209 \\ P_1 &= (508P_1 - 540P_2 + 488P_3 - 367P_4 + 144P_5 \\ &\quad - 24P_6)/209 \\ P_{N+1} &= (-24P_{N-5} + 144P_{N-4} - 367P_{N-3} \\ &\quad + 488P_{N-2} - 540P_{N-1} + 508P_N)/209 \\ P_{N+2} &= (-180P_{N-5} + 1080P_{N-4} - 2648P_{N-3} \\ &\quad + 3033P_{N-2} - 1960P_{N-1} + 884P_N)/209 \end{aligned} \quad (3)$$

Background

CIE tristimulus values can be calculated from spectral reflectance factors, spectral illuminant relative power distributions, and the CIE color-matching functions (CMFs). However, it is sometimes the case that the CMFs, for example, are available at intervals of 5 nm, but the spectral reflectance factors are available at intervals of 10 nm. Interpolation of spectral data may be required and interpolation methods therefore need to be considered.

A straight line can be drawn to fit exactly through any two points and a parabola through any three points. More generally, an n th-degree polynomial can pass through any $n + 1$ points. Imagine we wish to fit some spectral data $P(\lambda)$ at four wavelengths, λ_1 – λ_4 . We can write:

$$\begin{aligned} P(\lambda_1) &= a_1\lambda_1^3 + a_2\lambda_1^2 + a_3\lambda_1 + a_4 \\ P(\lambda_2) &= a_1\lambda_2^3 + a_2\lambda_2^2 + a_3\lambda_2 + a_4 \\ P(\lambda_3) &= a_1\lambda_3^3 + a_2\lambda_3^2 + a_3\lambda_3 + a_4 \\ P(\lambda_4) &= a_1\lambda_4^3 + a_2\lambda_4^2 + a_3\lambda_4 + a_4 \end{aligned} \quad (4)$$

which represents four simultaneous equations and four unknowns. In terms of linear algebra, Eq. 4 can be represented by Eq. 5:

$$\mathbf{A}\mathbf{p} = \mathbf{q} \quad (5)$$

where $\mathbf{q}$ is a 4×1 column matrix of reflectance values, $\mathbf{p}$ is a 4×1 column matrix containing the coefficients a_1 – a_4 , and $\mathbf{A}$ is a special 4×4 matrix

Interpolation of Spectral Data,

Fig. 1 Example of interpolating 20-nm spectral data (symbols) using a Lagrangian polynomial (solid line)

known as the Vandermonde matrix. In the example shown as Eq. 4, the Vandermonde matrix would be constructed with the entries thus:

$$\begin{pmatrix} \lambda_1^3 & \lambda_1^2 & \lambda_1 & 1 \\ \lambda_2^3 & \lambda_2^2 & \lambda_2 & 1 \\ \lambda_3^3 & \lambda_3^2 & \lambda_3 & 1 \\ \lambda_4^3 & \lambda_4^2 & \lambda_4 & 1 \end{pmatrix}$$

The polynomial in Eq. 4 is referred to as the Lagrange polynomial. It is trivial to solve Eq. 5 for the coefficients in **p** using MATLAB thus **p** = **A**\b or, alternatively, using MATLAB's *polyfit* function. However, the use of a Lagrangian polynomial in this way is not the best way to interpolate spectral data; the resulting polynomial may lead to wide excursions between the points [1].

Figure 1 illustrates a Lagrangian polynomial that was fitted to spectral data at intervals of 20 nm and interpolated at intervals of 1 nm. The interpolation is likely to be inadequate at the short and long ends of the spectrum.

One way to address this problem is to use a family of polynomials (each of which fits a relatively small number of points) rather than trying to fit the whole spectrum with a single polynomial. Repeated application of a low-order polynomial

to a restricted range of the data is an example of a "piecewise method." CIE Publication Number 15.2 recommends that interpolation of spectra be carried out using a third-degree polynomial from neighboring data within twice the measurement interval [2]. This means that a Lagrange interpolation formula should be used for four data points (two either side of the point to be interpolated). A later CIE publication [3] recommends one of four interpolation methods: (1) the third-order polynomial interpolation (Lagrange) from the four neighboring data points around the point to be interpolated, (2) a cubic spline interpolation formula, (3) a fifth-order polynomial interpolation from the six neighboring data points around the point to be interpolated, or (4) a Sprague interpolation.

Current Status

Sprague interpolation was recommended following a study by a CIE working group [1], and the method for doing this is defined by Eqs. 1 and 2. Figure 2 illustrates some spectral data at intervals of 20-nm Sprague interpolation at intervals of 1 nm.

The method can be used equally for reflectance factors or for illuminant spectral power distributions.

Interpolation of Spectral Data,

Fig. 2 Example of interpolating 20-nm spectral data (symbols) using the Sprague method (solid line)

Definition

Intrinsic imaging or intrinsic image decomposition is the problem of decomposing an image into two layers: the reflectance layer, which describes the albedo color of the material; and the illumination or shading layer, which contains information about the interaction between light and geometry. This decomposition is physically accurate for Lambertian materials, which reflect light uniformly independent on the observer's position. Obtaining this decomposition for single images is a highly ill-posed under-constrained problem, as for each known value of the input image, there are two additional unknowns. While still an open problem, since the 70s many methods have tried to tackle this problem by making assumptions or imposing priors over the layers. These priors might come from

different sources: studies of the human perception, statistics of natural images, user interaction, or directly learned from the data.

Overview

The appearance of an object in the physical world is determined by the complex interaction between the light, the material, and the geometry of the scene that contains it. Capturing this information in isolation for post-processing operations such as relighting or re-texturing can be done with different setups. The illumination is most frequently obtained by taking a light probe, which is 360° HDR picture of the environment. The material properties can be captured with different devices. Among such devices, the *goniophotometer* is the most accurate one to obtain the radiance under all possible combinations of incoming and outgoing light and view directions, capturing the behavior of the material in the form of Bidirectional Texture Functions. Finally, geometry can be obtained accurately with stereo cameras or depth sensors. These setups, however, require the use of specific devices and planning, and are not useful for on-the-wild situations where the only available device at hand is a conventional photographic camera.

When a light photon hits a pixel of the camera sensor, it integrates all the information that conforms the scene –geometry, materials and illumination– in a single value, making the problem of recovering back this data an ill-posed one. A typical strategy to obtain this latent information involves fitting an analytical function parameterized by geometry, light and material, problem which is known as *inverse rendering*. This estimated model will allow to fully modify and *re-render* the scene in post-processing, e.g., changing the illumination or viewpoint. The complexity of such model will determine the degree of realism of the matched scene, along with the difficulty in estimating its parameters, and the editing capabilities.

The intrinsic images model firstly introduced by Barrow and Tenenbaum [1], is a simple yet accurate way for inversely modeling the

appearance of a scene without the need to explicitly define the geometry or the illumination. Instead, it states that an image $\mathbf{I}$ captured with a conventional photographic camera can be represented as the pixel-wise multiplication of two images, as shown in Fig. 1b, where x is a pixel in the image, and $c \in \{R, G, B\}$ is the color channel or spectral band. The reflectance $\mathbf{R}$, or albedo, layer describes the diffuse color of the material and is invariant to illumination. The illumination layer $\mathbf{S}$ contains information about shading and shadows, and integrates the interaction between geometry and incoming light, usually containing also inter-reflections.

$$\mathbf{I}_c(x) = \mathbf{R}_c(x) \times \mathbf{S}_c(x) \quad (1)$$

In order to be physically accurate, this decomposition requires that the materials that compound the scene present Lambertian or diffuse reflection. That is, the reflected light (more technically, the surface luminance intensity) will be the same regardless of the observer's position, only obeying Lambert's cosine law. A huge number of materials in the real-world follow this property such as matte wall painting, unpolished wood, or freshly fallen snow. However, Lambertian reflections from polished surfaces are frequently accompanied by a specular or glossy reflection. The effect is maximally observed at the perfect reflection angle and falls off sharply. Several analytic models account for this effect such as Phong or Cook-Torrance. In the context of intrinsic decomposition, the specular highlights are usually accounted for as part of the shading layer, or less frequently, as an extra layer which is added to the initial ones, thus increasing the number of unknowns in the system.

Obtaining these components from a single image is a major challenge as for each known value of the input image there are two unknowns, therefore, infinite number of combinations that can satisfy Eq. 1 (e.g., Fig. 1d). To make the problem tractable, existing methods impose additional constraints or make certain assumptions about the components. In the following, the most common approaches are reviewed.

Intrinsic Imaging, Fig. 1 Intrinsic decomposition ambiguity (a–c) (inspired by [3]), and example of editing (d). (a) Input image **I**. (b) Decomposition into reflectance **R** (top) and shading image **S** (bottom). (c) Example of

ambiguity in the decomposition, the product of these two images also yields the same input image **I**. (d) Editing example: both layers have been modified separately and combined to alter the appearance of the input image

Priors and Methods to Constrain the Problem

Priors and constraints are some statistical tools and methods which are used to encode existing beliefs about a problem. In the intrinsic decomposition problem, several priors have been developed to help disambiguate the decomposition along with several assumptions and ad hoc user interfaces. From a general perspective, the type of constraints can be classified into: local constraints, such as those which operate at local neighborhoods around image pixels; global constraints, which extend the notion of neighborhood to any pixel in the image; and priors about the distribution of the values of each component—the shading, the reflectance, or the illumination. Besides, another type of classification can be done by analyzing the source of the knowledge which originated such constraints. This information might come: automatically from existing theories of the human vision and texture perception, defined by the user, or directly learned from

the data. In the following, the latter classification is developed in detail (see the state-of-the-art report of Bonneel et al. [3] for a more thorough evaluation with examples).

Automatic Priors

There exist a number of automatic priors that affect different aspects of the decomposition:

Shading: The initial techniques that addressed the intrinsic decomposition problem relied on theories of the human vision which relate local changes of intensity with either changes in reflectance or shading. The main theory was Retinex, which stated that the perceived color of an object remains constant as long as the reflectance ratios do not change, even if the light color changes. Inspired by it, Horn [8] implemented this theory in 2D images and presented a method to obtain the decomposition from black and white images assuming that sharp reflectance changes cause intensity discontinuities, while shading is a smooth

function. These types of constraints were implemented by thresholding local pixel derivatives to distinguish a change in reflectance from a change in shading.

Reflectance: The extension of Horn's work to colored images was done by Funt et al. [5] who associated changes in reflectance with local changes in chromaticity, and enforced integrability of the shading at these points like previous methods did. Propagating the shading values to their neighboring pixels was done by diffusion, solving the subsequent Poisson equation with a Fourier transformation. Later, several works extended this idea globally by assuming that the amount of different reflectances is sparse and performing color clustering within close-form or probabilistic frameworks [2, 6].

Texture: Textured areas provide a very strong cue about regions of the image which should have the same reflectance values. The challenge here lies in finding texture descriptors and similarity metrics among them which are invariant to changes in illumination and geometry. In an optimization framework, these constraints are imposed over both local and non-local areas of the image [12].

Lighting: The type of light that illuminates the scene is critical for its appearance. In general, most of the methods assume that the images are white-balanced, and illuminated by a single light source. This can be further constrained assuming that the scene is illuminated by a narrow-band sensor such as Planckian light or Daylight. In that case, the reflectance of a single object forms a line in log-chromaticity space. This has been implemented following the color lines model [10] or entropy minimization [7].

User Defined Constraints

Another set of techniques rely on automatic priors and user intervention. The first method to incorporate this kind of input into an optimization framework was Bousseau et al. [4]. They assumed that local reflectance variations lie in a 2D plane in RGB space, not containing black, and introduced three types of strokes with different semantics:

constant-reflectance, constant-illumination, and fixed-illumination. The result of this set of methods is pretty compelling, although creating the appropriate strokes for each image may be challenging for unskilled users.

Learning from Data

Finally, a well-known strategy to solve this problem consists of learning the constraints directly from the data. The first method using this kind of approach [11] used machine learning to classify the derivatives of the image as produced either by illumination or albedo. Ten classifiers were trained with a set of computer-generated images containing only reflectance or illumination components. Due to the high ambiguity, single classifiers were not enough, and they required to combine them with probabilistic propagation methods such as Markov Random Fields. As in many other fields in computer vision, deep learning methods have also marked a before and an after in the way this problem has been tackled. The leading strategies nowadays combine fully-supervised learning, using human-annotated and rendered datasets, with self-supervised learning, using multiple images of the same scene with varying illumination [9].

Applications

Having the intrinsic components is useful for any task that would require some knowledge about lighting or materials of the scene. For example, changing the materials of a scene is simplified to edit the reflectance layer; segmentation is improved if the reflectance layer is used instead of the original input image; or stylization and relighting can be done more accurately by optimizing the shading and reflectance components separately. An example of such edits is shown in Fig. 1d.

Iridescence (Goniochromism)

Richard J. D. Tilley

Queen's Buildings, Cardiff University, Cardiff, UK

Synonyms

[Goniochromatism](#); [Irisation](#); [Labradorescence](#); [Opalescence](#); [Pearlescence](#); [Polychromatism](#); [Schiller](#) (Note: these are not *exact* synonyms: they usually apply to specific examples of iridescence)

Definition

Iridescent is the adjective used to describe objects or surfaces that show bright, metallic-looking, shining colors that change noticeably as the position of the observer changes. Iridescence is the noun that describes the colors that arise from an iridescent object.

Description and Examples

The root cause of iridescence lies in the (coherent) scattering of white incident light by transparent or semitransparent surface and subsurface structures, as was stated by Robert Hooke in his description of iridescent peacock feathers [1]. He also gave a technique for distinguishing iridescent colors from those that are due to pigmentation – when the color is wetted, it will disappear if its origin is

refraction and reflection. For color to be observed, the substructures have to vary on a size scale equivalent to about half the wavelength of visible light. Moreover, iridescent reflections are often strongly polarized.

Among inanimate examples, colors of a soap film or films of oil on water can be thought of as archetypal [2]. A number of minerals such as labradorite and opal show iridescence and are used as gemstones. Materials that oxidize to produce thin transparent films overlaying a dark background also show strong iridescence, typified by silicon carbide (SiC) and bornite (Cu_5FeS_4) also called peacock ore. Dichroic filters, which are made by coating glass discs with multilayers of oxides, show iridescent colors. Dichroic glass, made in the same way, is used by artists. Iridescent gift bags and tags are commonplace, and iridescence is utilized in car paints, cosmetics, and other decorative and artistic objects. The iridescent reflected colors from CD and DVD storage discs and holograms used as security labels are familiar (Fig. 1a–c) [3–5].

Living organisms display an enormous variety of iridescent colors [6–11]. Many creatures are able to see near-ultraviolet radiation, and iridescence in the ultraviolet is of importance in the wild even though it is undetected by humans. Thin-film iridescence similar to that in soap films can be seen on close examination of the transparent wings of flies, bees and wasps, beetles, and many other flying insects. More obviously iridescent coloring is characteristic of many groups of birds (feathers), beetles (exoskeleton), and butterflies (wing scales), although iridescent colors are not restricted to these groups. In these cases the visual effect is often enhanced by backing the iridescent structures with a melanin-related black pigment so that stray reflections do not diminish the vividness of the perceived colors. Pearls and a number of shells show iridescence, notably that of the New Zealand paua, *Haliotis iris* (Fig. 1d–f).

In biological areas there is great interest in explaining the evolution and adaptive advantage of iridescent coloration. In photonics there is considerable effort expended in mimicking natural iridescence by artificially copying biological examples.

Mechanisms

The interaction of light with an iridescent surface alters the phases of the various components of the scattered radiation, allowing constructive and destructive interference to occur. Because phase shift is sensitive to the optical path through the membranes intercepted, the colors observed change dramatically with variation in viewing angle. The mechanism of color production is often described in terms of reflection or diffraction, and although such a clear-cut division is somewhat artificial, this provides a starting point for discussion.

Reflection

The simplest model for iridescence is the reflection of white light from a single transparent thin film, the cause of color in soap films and transparent insect wings (Fig. 1a, d). The phase shift that leads to interference and hence color production is between, in the simplest case, that part of the incident beam that is reflected off the top surface and that part that is transmitted through the film and reflected off the bottom surface (Fig. 2). At *normal incidence*, it is found that a monochromatic incident beam of wavelength λ reflected back from a thin film of refractive index n and thickness d in air or on a substrate of lower refractive index than the film will show constructive interference and so appear *bright* when:

$$2nd = (m + \frac{1}{2})\lambda \quad (m = 0, 1, 2, 3 \dots)$$

When the light is incident at a small angle to the normal, it is possible to use the *approximate* relationship:

$$2nd \cos \theta = (m + \frac{1}{2})\lambda$$

If the film is on a substrate of higher refractive index, the reflected light will show destructive interference and appear dark under the same conditions. Similarly, light reflected from a film in air

Iridescence (Goniochromism), Fig. 1 Iridescence (a) soap film; (b) labradorite; (c) wrapping paper; (d) ant wing; (e) scarab beetle; (f) paua shell decoration. (Photographs R J D Tilley)

or on a substrate of lower refractive index than the film will show destructive interference and so appear *dark* when:

$$2nd = m\lambda \quad (m = 1, 2, 3 \dots)$$

If the film is on a substrate of higher refractive index, the reflected light will show constructive interference and appear bright under the same conditions. When the light is incident at a small

angle to the normal, it is possible to use the *approximate* relationship:

$$2nd \cos \theta = m\lambda$$

Note that the equations for viewing at an angle do not take polarization into account and must be employed with caution.

To determine the appearance of a film illuminated with white light, the reflectivity has to be

Iridescence

(Goniochromism),

Fig. 2 Production of thin-film iridescent colors is due to the phase difference between rays reflected from top (*red*) and bottom (*blue*) surfaces

summed across all of the wavelengths in the visible. The result is that some colors will be suppressed because that particular wavelength will correspond to destructive interference, while those that correspond to constructive interference will be augmented, so that the film will appear colored. The colors seen depend upon film thickness and cycle through several series or *orders*. The $\cos \theta$ angle dependence given above indicates that as the viewing angle moves away from perpendicular, the color observed moves toward shorter wavelengths: a *blueshift*. Because the color observed depends upon the film thickness and angle of observation, in the case of unstable films such as soap bubbles, the colors swirl and change as the film thins and flexes.

Many decorative films and paints are made by using thin-film iridescence. On bags and gift tags, this is often a thin polymer film, sometimes containing a dye, overlaying a reflective substrate (Fig. 1c). Metallic car paints often contain flakes of a mineral such as mica overlaid with a thin film of a transparent oxide such as TiO_2 .

A similar effect, but generally with greater brightness, is found if the reflecting object is composed of multiple layers (often called multilayer stacks or distributed Bragg reflectors) consisting of alternating lamellae of higher and lower refractive index. The mineral labradorite (Fig. 1b) contains alternating lamellae of feldspars of slightly different constitutions, thus giving lamellae with different refractive indices. The iridescent colors of many scarab beetles (Fig. 1e) are due to a multilayer structure consisting of chitin and air

layers, while in paua shells (Fig. 1f), the color arises in layers of nacre, a composite of aragonite (CaCO_3) plates and proteins. The reflectivity of multilayers depends upon the thickness of the layers, their refractive indices, and the angle of view. Relatively simple formulas have been derived for the reflectivity of stacks where two layer types alternate, each of which is $\lambda/4$ thick (called a quarter-wave stack), viewed at normal incidence. The peak reflectivity of such a stack with refractive indices n_1 and n_2 and of thicknesses d_1 and d_2 occurs at a wavelength given by $2(n_1d_1 + n_2d_2)$. The optical behavior of more complicated arrangements, such as those found in dichroic interference filters and dielectric mirrors, can be calculated using computer software.

There are a number of differences between the colors exhibited by multilayers compared to those from single thin films. In particular, the blueshift observed as the observation angle moves away from normal to the stack is much less pronounced compared to single films.

Diffraction

Colors arise when white light is diffracted by objects with a dimension similar to that of visible wavelengths. For example, a single small hole, disc, speck, or droplet gives rise to diffracted beams in the form of nested cones with maxima and minima given by:

$$\sin \theta = m\lambda/d$$

Iridescence**(Goniochromism),**

Fig. 3 Irisation shown by high clouds. (Photograph R J D Tilley)

where d is the diameter of the object and m takes values of 0, the straight through beam; 1.220, first minimum (dark ring); 1.635, first bright ring (called the first-order diffracted beam); 2.333, second minimum (second dark ring); 2.679, second bright ring (second-order diffracted beam); and so on. For orders other than 0, the angle of scattering is wavelength dependent so that each diffracted cone will consist of a spectrum, with violet diffracted least and red the most.

A random distribution of scattering centers of differing sizes will not show iridescence as the orders overlap and cancel. However, if the collection is made up of similar-sized objects, iridescence can result. This occurs on rare occasions when high clouds are made up of uniformly sized droplets and viewed at an angle of approximately $10\text{--}45^\circ$ from the direction of the sun, a phenomenon called *irisation* (Fig. 3). The fact that strong iridescent colors are only rarely seen is likely to be due to the necessity of having uniform drop sizes with diameters of the order of 0.003 mm. Similarly, iridescence arising from small evenly sized spots and droplets that form on mirrors can sometimes be seen.

A surface which contains a series of equally spaced parallel grooves or slits with a spacing of about the wavelength of visible light forms a *one-dimensional diffraction grating*. Light incident upon such a grating of spacing d (either in transmission or reflection) will be scattered strongly in directions given by the *grating equation*:

$$d (\sin \theta_i + \sin \theta_m) = m\lambda$$

where θ_i and θ_m are the angles of incidence and diffraction, respectively, of the order m and θ_m is positive when the diffracted and incident beam lie on the same side of the grating normal and negative when they lie on opposite sides of the normal. Far from the grating, the (Fraunhofer) diffraction pattern will consist of a row of bright spots called *principal maxima*. The spacing of these spots is proportional to $1/d$ and lies along a line perpendicular to the grating grooves. They are separated by much smaller secondary maxima which will not concern us here as these do not give rise to strong iridescent effects. The zero-order, $m = 0$, diffracted beam is equivalent to an undeviated beam (transmission) or specular reflection (reflection). For the other orders, the angle of scattering, θ_m , is wavelength dependent so that white light will be spread out into a spectrum, with violet diffracted least and red the most (Fig. 4). The spectra produced by such gratings are intense, giving rise to marked iridescence (Fig. 1c).

Scattering centers can be distributed across a surface to form a *two-dimensional* grating. Such a grating can consist of an array of apertures arranged in an ordered pattern in an opaque screen, an ordered set of pits or protuberances arranged on a plane, and so on, most easily visualized for a rectangular array (Fig. 5a). Each row on the pattern acts as a one-dimensional grating,

Iridescence**(Goniochromism),**

Fig. 4 Iridescent color formation by a one-dimensional reflection diffraction grating

**Iridescence****(Goniochromism),**

Fig. 5 Iridescence from a two-dimensional diffraction grating: (a) grating can be envisaged as intersecting one-dimensional gratings; (b) diffraction pattern, with violet diffracted least and red most

and the diffraction pattern may be understood intuitively as arising from intersecting one-dimensional gratings. Each row will give rise to principal maxima (described by the grating equation) running normal to the row selected, separated by weak intermediary subsidiary spots that do not give rise to strong iridescence. A complete pattern will only be seen if the conditions of the grating equation are fulfilled for every row simultaneously. For a rectangular grating illuminated by a beam normal to the grating, the conditions for diffraction are:

$$a \sin \theta_m = m \lambda \text{ (grating spacing } a)$$

$$b \sin \theta_p = p \lambda \text{ (grating spacing } b)$$

(When this condition is met, all the other rows will be perpendicular to the incident beam.) Each diffracted order will now be specified by two indices m and p , so that:

$$d_{mp} \sin \theta_{mp} = mp \lambda$$

where d_{mp} is the spacing of the grating elements along the row giving rise to the diffraction pattern row containing the order mp . As before, the zero-order beam corresponds to undeviated transmission or specular reflection and is not colored. The diffraction orders, each forming a spectrum with violet diffracted least and red the most, will now be arranged on a grid with symmetry that matches that of the grating (Fig. 5b).

Many iridescent gift tags and bags show two-dimensional diffraction effects. The surface of these consists of a thin plastic film, often overlaying a reflecting layer. The polymer surface is embossed with several sets of grooves. Two sets at right angles give rise to square or rectangular diffraction effects, while three sets at 60° give rise to hexagons and star diffraction patterns.

Natural and artificial three-dimensional ordered crystal-like arrays of scattering centers, also called *photonic crystals*, are also known [12–14].

Iridescence (Goniochromism), Fig. 6 Diffraction by three-dimensional array of scattering centers

In this case diffraction is constrained by the spacing of the scattering centers in three dimensions. The condition for strong diffraction to occur is given by Bragg's law:

$$m\lambda = 2d \sin \theta_B$$

where m is the order of diffraction, d is the distance between the planes of scattering centers giving rise to the diffracted beam, and θ_B is the angle between the incident beam and the scattering planes (Fig. 6). As in previous examples, the position of all diffracted beams except for the zero order is a function of wavelength, and each diffracted order will be pulled out into a spectrum with violet diffracted least and red the most.

The most familiar natural object that displays such iridescence is the gemstone precious opal (Fig. 7). This consists of arrays of ordered silica spheres embedded in a matrix of amorphous silica. As the opal is tilted, the color observed moves to shorter wavelengths giving a blueshift. Artificial opals, also called colloidal opals, are made by sedimenting evenly sized polymer spheres. Under controlled conditions, these will pack into close-packed arrays as in natural opal and show typical opaline iridescence. If the spaces between the spheres are infiltrated with an inorganic material, typically an oxide such as TiO_2 or ZrO_2 , and the polymer subsequently dissolved, an array of close-packed shells forms. These show similar iridescence to natural opals.

Iridescence (Goniochromism), Fig. 7 Iridescent vein of opal in ironstone. (Photograph R J D Tilley)

If a structure forms in which the layers are composed of birefringent molecules, polarization of the scattered beam may occur. When the orientation of the molecules is such that there is an approximately constant rotation angle from one layer to the other, the diffracted light is circularly polarized. The color observed is given by Bragg's law, in which the pitch of the spiral is equivalent to d and the observed color changes with viewing angle as in the case of opals. This is found in a number of beetles and is exploited in liquid crystal thermometers.

Holograms

Iridescent colors that change hue and content dramatically with both viewing angle and viewing distance are produced by the holograms commonly seen as security tags on credit cards, banknotes, and many novelty gift items such as bookmarks, when viewed in white light. These are called rainbow holograms, Benton holograms, or white light transfer holograms.

Holograms are essentially interference patterns formed by the superposition of coherent light from a reference beam, and the same light after it has been scattered by an object. The "reconstructed" image is observed when the eye receives light from the reference beam alone that has interacted with the hologram. Holograms are

able to record both phase and amplitude information, so that the image contains considerable information content not normally inherent in an orthodox interference pattern. When conventional holograms are viewed in white light, each different wavelength produces its own distorted image of the object. These overlap and a satisfactory image is not observed. Rainbow holograms are produced by a sophisticated technique that allows undistorted colored images of the object to be viewed sequentially as the hologram is tilted. Each image of a single color appears as if viewed through a narrow slit. As the angle of observation changes, the virtual slit giving rise to the image changes, giving rise to different colors and different images.

Rainbow holograms are embossed on a thin plastic sheet by conventional embossing techniques. A master hologram is initially created, and this is copied to produce numerous metal “stamper shims” that are used in the embossing process. The interference pattern is recorded as complex series of ridges and whorls in the transparent film. To create an image, white light passes through the film containing the interference pattern and is reflected back from the backing to pass through the hologram again before reaching the eye. Passage through the holographic structure imposes a phase change on the components of the light which is interpreted as described.

Suppressed Iridescence

Many creatures, especially insects and birds, show shining metallic reflections with all of the characteristics of iridescence except that there is no significant change of hue with viewing angle, as if the iridescent color changing ability has been suppressed. These non-iridescent or suppressed iridescent colors arise in similar ways to iridescence, from coherent scattering of incident white light. The change in the optical effect is due to a change in the nanostructural organization of the scattering materials. For example, ordered high reflectivity stacks give rise to noticeable iridescence. As the stacks become less well ordered, due to refractive index variation or an uneven distribution of layers, the single angle-dependent color reflected is replaced by a shining single color that is fairly constant over a wide range of angles (Fig. 8a). If the layers in the stack are very disordered, omnidirectional metallic silver reflection is produced (Fig. 8b).

Similar complexity modifies the diffraction characteristics of diffraction grating iridescence. As an ordered grating becomes replaced by structures of a quasicrystalline nature, made of interconnected sheets, pillars, tubes, or globes of chitin or β -keratin, the characteristic angular-dependent iridescence may be replaced by a single shining color that does not change significantly with viewing angle (Fig. 8c). In many of these

Iridescence (Goniochromism), Fig. 8 Suppressed iridescence: (a) rose chafer, *Cetonia aurata* (Photograph Ralph Hobbs, 28 April 2010, Lewes, E. Sussex., with permission), (b) silver markings on the underside of the

natural nanostructures, Fourier transform analysis shows that short-range order is important in color production.

In some cases iridescence appears to be suppressed because the scattering medium is composed of slightly misaligned microdomains. At any particular angle of incidence, only some of the microdomains reflect coherent light which is brightly colored. As the viewpoint is changed, some of these are extinguished, while others shine out. The uniform non-iridescent shining color is the macroscopic effect of the microdomains winking on and off as the angle changes. This augments the suppressed iridescence in many blue butterflies of the lycaenid family (Fig. 8c).

Itten, Johannes

David Briggs¹ and Stephen Westland²

¹Short Courses, National Art School, Sydney, NSW, Australia

²Colour Science and Technology, University of Leeds, Leeds, UK

Johannes Itten was a Swiss expressionist painter, designer, and teacher and one of the main pedagogical forces behind the Bauhaus in its earliest phase. His 1961 book *The Art of Color* presented color theory in a simplified form that largely excluded scientific developments from the mid-nineteenth century onward. This simplified approach has permeated much subsequent teaching of color in art and design.

Itten was born in Södern-Linden (Switzerland) on 11 November 1888. He trained and practiced as a teacher in Bern before studying under the abstract painters Eugène Gilliard in Geneva (1912) and Adolf Hoelzel in Stuttgart (1913–1916). He then ran his own art school in Vienna until the director of the Bauhaus in Weimar, Walter Gropius, appointed him as one of its first teachers in 1919. Itten played a key role in the development of the “preliminary course” that would teach students the basics of material characteristics, composition, and color. However, conflict involving Itten’s ambitions, his promotion of the eastern-inspired Mazdaznan sect, and his opposition to involvement in commercially oriented design, by which Gropius hoped to validate the state-funded Bauhaus in a hostile political and economic climate, prompted Itten to leave in 1923. He subsequently taught in the Mazdaznan community in Zurich (1923–1926) before establishing an art and architecture school in Berlin (1926–1934) and directing the Advanced Vocational School for Textile Art in Krefeld (1932–1938). Itten then settled in Zurich, serving as director of the Museum and School of Applied Arts (1938–1953), the Silk Industry Vocational School (1943–1960), and the Rietberg Museum (1949–1956).

In his retirement, Itten published his main book on color theory, *The Art of Color*, in 1961 [1–3] and an account of his Bauhaus preliminary course, *Design and Form*, in 1963 [4]. Some of his earlier ideas on color had appeared in the rare hand-printed *Tagebuch* of 1930 [5] and *Die Farbe*, an exhibition catalog from 1944 [6].

Color Star, Color Circle, and Color Sphere

At the Bauhaus Itten taught color theory using his *Farbenkugel* (color sphere) lithograph, which included a “color star” of radiating tint and shade scales (Fig. 1). Its 12-hue scale was derived via Hoelzel from one that Bezold had proposed as being perceptually even, but was modified to align what Itten regarded as the warm-cool boundary (between yellow and yellow green) vertically. Unlike this 1921 scale, which placed yellow, “purple” (magenta?), and cyan-blue in a symmetrical triad, Itten’s 1961 color diagrams were all structured around a symmetrical triad of perceptually pure red, yellow, and blue “primary” hues, producing an unequal hue scale with larger perceptual steps in the yellow-green-blue sector. Three “secondary” hues (orange, green, and violet) and six intermediate “tertiary” hues (red-orange, yellow-orange, etc.) complete the 1961 hue scale. This change reflects Itten’s adherence to the view, widely held in science until the mid-nineteenth century, that all object colors are mixtures of red, yellow, and blue primary colors. For a three-dimensional model, Itten (1961) continued to ignore the quantitative systems devised by Munsell and Ostwald and retained a simple spherical model externally resembling the one published by Runge in 1810. This spherical model places the strongest colors of all hues on the equator, with the result that the vertical dimension does not represent lightness consistently.

Color Contrasts

Hoelzel incorporated a broad range of sources into a system of seven or eight “contrasts” of color that were central to his teaching. Itten simplified Hoelzel’s classification and language into a list of seven contrasts that is one of the most widely cited elements of his system: contrast of hue, of light and dark, of cold and warm, of complements, of saturation, of extension, and simultaneous contrast.

Itten, Johannes,

Fig. 1 Itten's color star diagram of 1921, numbered to show literal English translations of the German color names. From its position between purple-violet and crimson, "Purpur" might reasonably be interpreted as a magenta. Subjective and "Objective" Color Harmony

Itten encouraged exploration of the color preferences of the individual, but warned that this "subjective harmony" must often be subordinated to "objective" (though scientifically unexamined) laws. "Objective" harmony required balance of the three traditional primaries, which could be obtained (following Hoelzel) from complementary pairs, equilateral and isosceles triads, and rectangular, square, and trapezoidal tetrads in his 12-hue circle, but also by tilting these shapes in any direction within his color sphere. Balance also required that the three primaries be present in a set

ratio that Hoelzel had derived ultimately from Schopenhauer [7], but which Itten misattributed to Goethe. Unbalanced, "discordant" combinations could however be used for expressive effect.

Color Expression

Itten also regarded color expression as involving objective rules and presented a system of dictionary-type meanings of colors and color combinations, in which complementary colors were expected to have opposite meanings, secondary colors were expected to combine the meanings of the primaries they "contain," and

meanings could be modified by contrast effects with surrounding colors.

Ives, Frederic Eugene

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Ives was born on February 17, 1856, in Litchfield, CT, to Hubert L. Ives and his wife Ellen. His father passed away when Frederic was still a child. He left school when he was 12 and began an apprenticeship as printer at the *Litchfield Enquirer*. Photography and engraving became his hobby. At age 18, based on his reputation and without having a formal education, he was invited to run the photography laboratory at Cornell University in Ithaca, NY, where he stayed for 4 years, a key period in regard to his inventions. While at Cornell he invented a practically valuable method of the halftone printing process for black-and-white photographs [1]. In 1879 he got married and moved to Philadelphia where he established an association with a major manufacturer of woodcut engravings who was interested in photographic reproduction methods and Ives' halftone process. Until 1880, illustrations in books, magazines, and newspapers were largely based on woodcuts as well as lithography; by the turn of the century, the industry had mostly switched over to Ives' halftone process.

ITULAB

► [CIELAB for Color Image Encoding \(CIELAB, 8-Bit; Domain and Range, Uses\)](#)

Ives was issued a total of 70 patents in his lifetime, the earliest related to his halftone printing process and many related to trichromatic halftone printing. He revolutionized color printing in books, magazines, and newspapers in a manner similar to that for black-and-white printing. Up to that time the process in commercial use of color

printing was lithography, with the image constructed from up to a dozen handmade limestone or metal engravings used to print with differently colored inks. He regularly lectured on the subject of his inventions at Philadelphia's Franklin Institute. Circa 1890 he moved to New Jersey, outside New York. Frederic Eugene Ives died on May 27, 1937, in Philadelphia, Pennsylvania. His portrait was attached to a postage stamp celebrating his invention of the halftone process (Fig. 1) [2].

F. E. Ives' son Herbert obtained a PhD degree from Johns Hopkins University in 1908. He was also active in the field of color science, publishing in 1915 an important article on the transformation of color-matching functions between different colorimetric systems [3].

Major Accomplishments/Contributions

Ives was granted patents covering the halftone process in 1881 [4]. In 1890 he obtained a patent for his "trichromatic" color photography process

Ives, Frederic Eugene, Fig. 1 US postage stamp celebrating Ives' invention of the halftone printing process, 1996 (Copyright The U.S. Government)

Ives, Frederic Eugene, Fig. 2 Stereoscopic color image as viewed in the Kromskop, 1897. On the left are the B&W stereoscopic images for the three primary colors as used in the Kromskop. *Top right* is a digital recreation of the two stereoscopic versions of the image. On *bottom right* is an enlarged version of the image based on a photographic print made in the 1950s

[5] and in 1892 for a related camera [6]. There were two steps to Ives' halftone color printing process: (1) Color separations were obtained by making successive exposures through colored filters onto film, and halftone plates were made from these filtered exposures. (2) The three separations were printed onto paper, on top of each other in exact registration, with yellow, magenta, and blue-green inks [7]. Unlike the system proposed for color photography by J. C. Maxwell in 1855 [8] using red, green, and blue filters, Ives learned from experiments that the most accurate results were obtained when using yellow, magenta, and cyan (blue green) as primaries. This process and further developments resulted in a revolution of the technical methods of printing colored images.

In 1894 he obtained a patent for the Kromskop (Fig. 2), a stereoscopic version of his trichromatic camera [9]. It had limited success, and some years later, Ives transferred the related patents to the Eastman Kodak Company where they were used to develop the Kodachrome process. Two more significant inventions were a portable "colorimeter" and the "photometer," both patented in 1908.

The former was used to measure and define color stimuli in terms of trichromatic designations, the latter to obtain measures for hue and intensity of lights. In 1909 and 1911 Ives was granted patents for the Tripak paper color film, used in the Tripak color camera [10].

Judd, Deane Brewster

Michael H. Brill¹ and Rolf G. Kuehni²

¹Datacolor, Lawrenceville, NJ, USA

²Charlotte, NC, USA

Deane Brewster Judd (1900–1972) was an American physicist who contributed to the fields of colorimetry, color discrimination, color order, and color vision. Born in South Hadley Falls,

Massachusetts, he attended Ohio State University and Cornell University and received there a Ph.D. in physics in 1926. He was a Munsell research associate in colorimetry at the National Bureau of Standards (NBS) in Washington in 1926.

In 1927 Judd joined the NBS, where he remained until his retirement in 1969 and subsequently continued as a guest worker. He was the USA's representative in colorimetry at eight meetings of the International Commission on Illumination (CIE) from 1931 to 1967 and thereby a key force in the development of the CIE standard system of colorimetry, e.g., 1931 and 1964 standard observers, standard illuminants B and C, daylight illuminants like D65, and definition of colorimetric purity [1]. Largely responsible for coining the term “psychophysics,” he wrestled throughout his career with the relationship between color stimuli and color perception.

Colorimetric System

Judd introduced the concept of keeping luminosity and chromaticness separate in the CIE system. He was active in the colorimetric definition of color temperature and introduced the CIE colorimetric system to US industries. Together with D. L. MacAdam and G. Wyszecki, in 1964, he used principal component analysis to show that natural daylights are largely composed of three components from which daylights at any correlated color temperature can be defined (CIE method of calculating D illuminants) [2].

Color Difference

In a series of papers in the 1930s, Judd represented then-available color-scaling data first into a chromaticity diagram based on color-matching functions introduced by the Optical Society of America in 1922, then represented the resulting diagram in a Maxwell-type primary triangle, and finally embedding unit difference ellipses into the CIE chromaticity diagram. This work became the basis for the CIE (u,v) color diagram in 1960, slightly modified in the 1976 CIELUV color space. In 1939 he was instrumental in developing the NBS color difference formula. When in 1947, at the suggestion of the US National Research Council, the Optical Society of America (OSA) undertook to develop a perceptually uniform color space. Judd became its chairman and remained in that position until 1968, when D. L. MacAdam assumed the chairmanship, with results published in 1974. One of the key findings was “that strictly uniform color scales of all kinds are not homologous with Euclidean space” to which Judd proposed a solution implemented in the OSA Uniform Color Space [1].

Systematic Color Names

The perceived need for systematic naming of colors resulted in 1939 in ISCC-NBS Method of Designating Colors, based on the Munsell color system, with a revised edition published in 1955 [3, 4].

Color Constancy

Judd presented on color constancy first in 1940. He then presented with Helson and Warren, in 1952, results of meticulous work on the subject [5, 6].

Miscellaneous

At NBS Judd investigated impaired color vision, whiteness measurement of paper, opacity, color

stimulus measurement, and a flattery index for artificial light sources. In 1951 he proposed a modification of the CIE 1924 luminous efficiency function $V(\lambda)$ below 460 nm that became known as Judd-modified $V(\lambda)$, not implemented in the CIE system but used in some vision research works [7]. In addition to his positions at the CIE, Judd was president of the Optical Society of America from 1953 to 1955 and of the Inter-Society Color Council from 1940 to 1944. He was president of the Board of Trustees of the Munsell Color Foundation from 1942 to 1972.

In his homage, the International Colour Association (AIC) instituted its Judd Award, a prize that since 1975 is bestowed every 2 years to persons who have made relevant contributions in color research.

Judd was the author of one book [8] and more than 200 articles, 57 of which were reprinted as a volume by the NBS [1].

K

Katz, David

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Image source: University of Rostock, Germany

Katz was born on October 1, 1884 as the seventh of eight children of his parents in Kassel, Germany, where he attended the local Realgymnasium. As a child and student, he became a talented amateur

painter, interested in color and other sensory abilities. In 1902 he began studying at the nearby University of Göttingen. There he became interested in psychology taught by G. E. Müller. In 1906 he obtained a PhD degree in psychology, physics, and philosophy, and in 1907 he assumed the position of assistant to Müller. In 1911 he was named a professor, based on his work on color phenomenology [1]. From 1914 to 1918 he was a volunteer soldier in the German Army. In 1919 he received an invitation from the University of Rostock to assume a then new professorship in psychology. In the same year he married the psychologist Rosa Heine with whom he had two sons. Over the years they both were active in a wide field of psychology, including that of children and animals and had a number of well-known students. In 1929 Katz was for a time a guest professor in Maine in the USA. Shortly after Hitler's move to power in 1933, Katz and his wife were officially retired from their positions. In the same year Katz, with the help of a colleague, moved to England, followed a year later by his wife and sons. In 1937 Katz received an invitation to fill the first professorship in psychology in Sweden at the University of Stockholm. Here he was broadly active in many fields of psychology. In 1952, already retired, he received an honorary professorship from the University of Hamburg. On February 2, 1953, he died in Stockholm. Katz produced over 200 research papers and books, most in the general field of psychology [2].

Major Accomplishments/Contributions

Beginning with his dissertation, Katz was specifically interested in the phenomenology of vision, including shape, structure, space, color, and movement, to the exclusion of related physics and psychophysics. He defined three appearance modes of colors: film colors, surface colors, and volume colors. Film colors are those experienced when looking into the black tube of a spectroscope and seeing spectral colors, having a slightly spongy appearance without having a specific location in space. Surface colors are those commonly referred to as object colors. Volume colors he defined as those of colored glasses or gelatins. An important concept in his work was the subjective gray we experience either with closed eyes in the absence of strong light or with open eyes in a completely dark room. Another one was the reduction screen, a black sheet of paper with a small hole through which a small section of a colored object could be viewed and the resulting film color appearance compared to the surface color without the screen. Katz and his students performed many experiments related to color appearance involving illumination changes, surround and shadow effects, monocular versus binocular vision, exposition time, color constancy and lack thereof, light and dark adaptation, color and depth contrast effects, and the effects of chromatic illumination, to name a few. He introduced novel concepts, translated as “pronouncedness” and “insistence,” to describe nuanced phenomenological color effects. A key subject was the problem of definition of the “true” color of an object. To measure phenomenological magnitudes, he used innovative disk mixture methodology.

In his book [1] Katz discussed his agreements and disagreements with other researchers and their findings, such as Hering and of his time K. Bühler, A. Gelb, E. Jaensch, J. von Kries, and E. G. Müller. An important psychological concept of that period was Gestalt psychology based on the idea that, as its primary formulator M. Wertheimer expressed it, “the brain is holistic” by considering in assessing a given situation the total amount of information received. Together with self-organizing tendencies, this results in “the whole is greater than its parts.” Katz published a textbook on the subject in 1944, issued in several editions and multiple languages [3].

Katz’s book of 1911 was issued in a revised and updated version as *Der Aufbau der Farbwelt* (The constellation of the world of colors) in 1930 [4]. After he moved to London a shortened, translated version was published in 1935 in England as *The world of colour* [5].

Kohlrausch, Arnt

Rolf G. Kuehni
Charlotte, NC, USA

Portrait © Jürgen Killmann and Universität von Tübingen, 1969

Biography

Arnt Kohlrausch was born on October 30, 1884 in Hannover, Germany, a member of an extended family of scientists from the early nineteenth century to the present. His father was professor of electrical technology at the Technical College of Hannover. Arnt Kohlrausch studied medicine at the universities of Marburg, München, and Rostock, graduating in 1911. In 1918 he became lecturer in physiology at the University of Berlin. In 1926 he moved to the University of Greifswald, today in the German province of Mecklenburg. In 1928 he became chair of physiology at the University of Tübingen, where he remained until his retirement in 1951. Kohlrausch was active in several fields of physiology. Perhaps his best-known work is *Körperliche und psychische Lebenserscheinungen* (Bodily and psychological phenomena of life) [2]. He also did research in visual perception and was one of the founders of the journal *Die Farbe* (Color). A peculiarity of low-level brightness perception, the *Kohlrausch-Knick* (bend) is named after him. It refers to a bend in the curve of absolute luminance threshold versus time during dark adaptation, the bend being due to the crossover of absolute thresholds of rods and cones as a function of time. The perceptual effect on an observer is that a very dim scene suddenly appears brighter as the rod sensitivity rises enough to dominate the visual signal. In English it is known as the “rod-cone break.” Kohlrausch died on July 13, 1969 [1].

Major Accomplishments/Contributions

In 1923 Kohlrausch published an article *Über den Helligkeitsvergleich verschiedener Farben, Theoretisches und Praktisches zur heterochromen Photometrie* (Comparing brightness of different colors, theoretical and practical aspects of heterochromatic photometry) [3] in which he investigated in detail the effect of hue on perceived brightness, mentioned earlier by Helmholtz [4]. This was followed in 1935 by the article *Zur Photometrie farbiger Lichter* (Photometry of colored lights) [5]. As reported by D. B. Judd [6], in 1939, J. Urbanek and E. Ferencz introduced the term Helmholtz-Kohlrausch effect for the phenomenon, a term still in use today [7]. Figure 1 shows some examples. The six circles have luminance values identical to that of the achromatic surround. To most observers the circles appear, to various degrees, lighter than the gray of the surround.

Helmholtz used the term *glühend* (glowing) to describe the appearance of the chromatic colors compared to the achromatic surround. The strength of the effect varies by hue. Quantitative investigations of the Helmholtz-Kohlrausch effect (HKE) based on the CIE colorimetric system were performed by Wyszecki and Sanders in 1964 [8], the basis of the inclusion of the HKE in the lightness formula of the Optical Society of America Uniform Color Scales [9].

Kries, Johannes Adolph von

Mark D. Fairchild

College of Science, Rochester Institute of Technology, Rochester, NY, USA

J. v. Kries

Johannes von Kries was a German physiological psychologist, or what might now be called a neuroscientist, and student of Helmholtz. In color science, he is known as the father of chromatic adaptation models for his work on the coefficient theory of adaptation. He also made significant contributions to a variety of areas including probability theory and the structure of the retina and human visual system [1].

von Kries published profusely (in German, with few works translated to English) on topics such as blood flow in arteries, duplicity theory, chromatic adaptation, zone theory, probability theory, physiology, psychology, and history. For example, observations of the Purkinje shift led von Kries to postulate the existence of two separate visual systems, rods and cones, also referred to as duplicity theory. It is well known that Helmholtz described the trichromatic theory of color vision and participated in a famous academic dispute with Hering, the main proponent of opponent-colors theory. It is less widely recognized that von Kries was among the first proponents of the so-called zone theory of color vision that allowed for trichromatic receptors (the cones) and opponent processing of the visual information. It is little wonder that von Kries is sometimes referred to as the “greatest German disciple” of Helmholtz. Considering that Helmholtz’s students included the likes of Max Planck, Wilhelm Wien, Arthur König, A.A. Michelson, and Wilhelm Wundt, that is quite a statement indeed.

In the second half of the nineteenth century, von Kries was applying probability theory to the evaluation of the effectiveness of new drugs. He realized that the computation of probability distributions depends on the classification of symptoms and pathologies into diseases, often very subjective data. Given that the important uncertainty was determined by the experimenters’ definition of events, he developed the logical foundations of a probability theory where the subjectivity of mental representations impacts the assignment of numerical values to probabilities. Interestingly, with some distortion and misunderstanding, these ideas passed on to Keynes and formed the

core of his economic theory. In his book on the topic, von Kries developed a highly original interpretation of probability, illustrating it to be both logical and objective.

Returning to color science, von Kries' most recognized and long-lived contribution came from his works on the theory of chromatic adaptation (1902, 1905) [2, 3] in which he proposed the coefficient rule that lives on to this day as the von Kries coefficient law or simply the von Kries model of chromatic adaptation. Interestingly von Kries did not write out the mathematical formula with which he is credited; he simply stated the theory in words. In MacAdam's translation of von Kries' (1902) words:

This can be conceived in the sense that the individual components present in the organ of vision are completely independent of one another and each is fatigued or adapted exclusively according to its own function.

Perhaps it shouldn't be too surprising to realize that von Kries (1902) himself foresaw that this model was too simple to explain all chromatic adaptation phenomena. The next line after his description of what is now referred to as the von Kries model reads:

But if the real physiological equipment is considered, on which the processes are based, it is permissible to doubt whether things are so simple.

Indeed things are not so simple, yet von Kries' theory forms the basis of all effective modern models of chromatic adaptation, including that embedded in CIECAM02.

Kruithof Curve

Wout van Bommel

van Bommel Lighting Consultant, Nuenen, The Netherlands

Definition

“Kruithof's graph,” as published in 1941 by Kruithof, that shows, for general lighting in interiors, what combinations of illuminance level and correlated color temperature result in a “pleasing” or “not pleasing” assessment by persons in that interior.

Preferred Correlated Color Temperature (CCT) for General Lighting in Interiors

Around the time of the introduction of tubular fluorescent lamps in the early 1940s, Kruithof was the first who carried out a study on preferred correlated color temperature (CCT) for interior lighting. He investigated the relationship between lighting level in an interior and the CCT of the light sources used, on the assessment of people in terms of pleasantness [1]. His study received much recognition, although many subsequent researchers got inconsistent results. It must be realized that not only the lighting level but aspects as climatic conditions and cultural background influence the preferred illuminance as well.

Lighting has not only a visual effect but also a nonvisual biological effect that influences health and well-being. The CCT of lighting plays an essential role in the effectiveness of lighting for the latter aspect. This relatively new knowledge has led to dynamic interior lighting installations where both the lighting level and the CCT gradually change in the course of the day [2]. This, together with the availability of LED light sources with a wide range of CCTs, has given rise to renewed interest in the research of Kruithof and other researchers, on preferred CCT in interior lighting.

CCT and Lighting Level

The purpose of the 1941 research of Kruithof, then one of the early developers of tubular fluorescent lamps, in fact, was the determination of the fluorescent powder composition for the production of commercial fluorescent lamps. Note that at that moment of time, manufacturers planned to bring fluorescent lamps on the market with only one or only very few types of fluorescent powder. Kruithof’s pleasantness assessment tests were carried out with observers in a room where the lighting level and the CCT of the light sources used could be changed independently. He presented the results in a graph shown in Fig. 1. Here the area in between the two curves represents illuminance level and CCT combinations that result in lighting that is judged as “pleasant.” The area above the upper curve represents the judgment “too cold” and the area under the lower curve “too dim.”

The conclusion of Kruithof is straightforward: at low illuminances, low CCT light sources

should be used and, at high illuminances, high CCT light sources. As the big market for fluorescent tubes in that era was in offices and industries where relatively high illuminances were needed, the first fluorescent tubes on the market indeed had relatively high CCTs of at least 4000 K. Another reason for these relatively high color temperatures was the fact that higher CCT lamps could be produced more efficiently.

Kruithof’s results have often been used to draw general conclusions on preferred CCTs in interior lighting design. In this context, however, it is important to note some details of his research:

- Kruithof’s graph is based on a pilot study in which only two observers participated [3].
- The research has been carried out in a laboratory setting.
- Kruithof used fluorescent lamps with different fluorescent powder compositions for the mid-range of CCTs; for the lower CCT range,

Kruithof Curve, Fig. 1 Kruithof’s graph with combinations of illuminance levels, E, and correlated color temperatures, CCTs, that are judged as “pleasant.” Logarithmic

E scale and inverted reciprocal CCT scale, as in Kruithof’s original black and white graph [1]

incandescent lamps on a dimmer; and for the higher CCT range, daylight or daylight luminance lamps. This means that the color-rendering qualities of the light sources used in his test were widely different. This may have had a considerable influence on his results.

- The observers had a short habituation time for each different situation. Recent research into the acceptance of extreme high CCT values of up to 17,000 K shows that a habituation time of some 1–2 weeks influences the acceptance of CCTs [4].
- The research has been carried out in the Netherlands (Mid-Europe). It is known that the climatic conditions and the cultural background of the observers play a role in the preference of CCT values (see next sections).

Since the publication of Kruithof, many other researchers at many different institutions have carried out investigations on the same theme. Many of them gave less straightforward conclusions [3, 5]. With the introduction of LED light sources with a wide range of CCTs for the lighting of interior spaces, the subject has received renewed interest. Again the research results are, to some degree, conflicting. Often the research results validate the statement that the use of high CCT lamps at low illuminances results in unpleasant assessments. However, low CCT lamps do sometimes result in pleasant situations when used at higher illuminances, and some studies show a general preference for the use of lower CCT lamps [6].

Based on a literature search, Fotios [7] concludes that 29 studies were published in which Kruithof's relationship was the subject of investigation. He evaluated the experimental design and quality of reporting of these studies. On this basis, only nine studies passed the test of credibility. Fotios further evaluated these nine studies resulting in his suggestion that variation in CCT (within the range of approximately 2500–6500 K) does not affect pleasing conditions. With all the knowledge gathered since Kruithof carried out his

test in 1941, the conclusion can only be that the Kruithof curves are not valid for general use.

CCT and Climatic Conditions

The predominantly prevailing climate also has an influence on the preference for color impression in interiors. In a warm climate, the preference is more toward light sources with higher CCTs, while in colder climates, preference is more for lower CCTs. These preferences are confirmed by sales analysis of the various color types of fluorescent tubes per region. With the availability of dynamic lighting installations with which CCT can be varied, sometimes the CCT during the winter and summer season is varied according to the above rule, especially in shop lighting.

CCT and Cultural Background

The cultural background plays, probably because of longtime habituation, a role in the acceptance and preference of both CCT and light levels. A typical illustration is Japan, one of the few countries in the world where fluorescent tubes have been used in domestic lighting, right from the beginning of their introduction in the 1940s. These lamps were originally only available in CCT versions of around 4000–5000 K. Today, in Japan, a preference for higher CCT lamps is seen than in other countries with similar climatic conditions where the standard in domestic lighting was incandescent lamps with relatively low CCTs.

CCT and Nonvisual Biological Effects

The eye has light-sensitive cells (intrinsic photo-sensitive retinal ganglion cells) that connect with the biological clock (suprachiasmatic nucleus) in the brain, which in turn connects with the pineal gland that controls for a part the rhythm of the hormone metabolism. Through these pathways, light has a nonvisual biological effect that influences health and well-being. The intrinsic photo-sensitive retinal ganglion cells have a high sensitivity in the blue part of the spectrum. Cool-white light of a high CCT has, therefore, a more significant nonvisual biological effect than light

with a large red component warm-white light of low CCT.

This relatively new knowledge has already led to two new developments in lighting, especially in office, industrial, school, and hospital lighting:

- Dynamic lighting installations that automatically vary the lighting level and CCT in the course of the day to get, at the right moments, biologically activating and relaxing effects
- The introduction and use of extreme high CCT lamps with good color rendering ($R_a > 80$) for use in interior lighting installations (e.g., in dynamic installations as described above)

These developments will probably also have a meaning for the preferred CCT in interiors.

Kubelka, Paul

Michael H. Brill¹ and Michal Vik²

¹Datacolor, Lawrenceville, NJ, USA

²Faculty of Textile Engineering, Laboratory Color and Appearance Measurement, Technical University of Liberec, Liberec, Czech Republic

Paul Kubelka (1900–1954) was a Czechoslovakian chemical engineer whose many accomplishments include a theory of light absorption and scattering by a layer of paint. That theory, originally published in 1931 with Franz Munk [1], underlies much software that performs colorant recipe prediction (colorant formulation). Whereas the 1931 theory assumed that light flows in one dimension (two fluxes, upward and downward within the layer), in 1948 Kubelka derived the same equations (up to a factor of 2) assuming spherical scatter within the paint layer [2]. Later he generalized the theory to inhomogeneous layers [3].

The main contribution of these articles was a closed-form function relating the reflectance R of a layer to two constants characteristic of small particles within the layer: the absorption

coefficient K and the scattering coefficient S (both assessed in a unit thickness of the layer). If the layer is opaque, then the reflectance is a function of K/S , otherwise R depends on K and S separately, as well as on the reflectance of the material behind the layer. The Kubelka-Munk analysis also includes equations for total transmittance of a translucent layer.

Although Kubelka and Munk independently developed their analysis for paint layers, the underlying theory originated with an astronomical motivation, starting with Arthur Schuster's 1905 paper [4] relating to transmission of light through clouds.

To render Kubelka-Munk analysis useful for colorant formulation, one needed the additivity principle described by Duncan in 1940 [5]. This principle says that the total absorption coefficient K of a layer is the concentration-weighted sum of the K values of the components ($K = c_1 K_1 + c_2 K_2 + \dots$) and similarly for S ($S = c_1 S_1 + c_2 S_2 + \dots$).

Once the Kubelka-Munk theory, the additivity principle, and computer technology had emerged, colorant formulation was on its way. By 1958 Davidson and Hemmendinger introduced the analog Colorant Mixture Computer (COMIC), and this was quickly followed by dedicated digital devices, which in turn yielded to software packages that ran on general-purpose digital computers.

The above discussion places Paul Kubelka's color-science contribution in historical context. His life story offers an interesting context as well (see his 1947 autobiography <http://www.graphics.cornell.edu/~westin/pubs/kubelka-autobio.html>, accessed 8 Jan 2014).

Kubelka was born in 1900 to Austrian parents in Czechoslovakia. He was educated in the German language and attended elementary school in Kladno and secondary school in Brno and Prague. In 1918 he served half a year in the Austrian Army and began studies at the Technical University in Prague. In 1922 he passed his final examination as a chemical engineer. He then served seven months in the Czechoslovakian Army, where he soon commanded the military analytical laboratory. He also worked with L. Storch, professor of physical chemistry at the Technical University.

After leaving military service, Kubelka collaborated with Werner Mecklenburg, the well-known colloid chemist, at Verein für Chemische und Metallurgische Produktion, in Aussig (SPOLCHEMIE, in Ústí n. L.), Czechoslovakia. During this period, he worked on activated charcoal, resulting in patents and in the gas mask charcoal "G 1000." One theoretical investigation of this period earned Kubelka a doctorate of engineering in 1926.

During this time Kubelka married Margarethe Schönhöfer and had two children.

In 1928 he led both the Inorganic and Analytic laboratories in Ústí n. L. His laboratory investigated (among other things) high temperature reactions, the preparation of pigments, and activated charcoal.

In 1931 Kubelka resolved to enter an academic career. Because of his publication on absorption and capillary condensation, he was nominated docent of the University of Prague. There he investigated the absorption of vapors by silica gel, which led to an exact method of measurement of surface tension of crystals. His work interested Fritz Haber, and he expected to be nominated as professor at a German University. (It was during this year that Kubelka published the famous paper with Munk, but he does not mention this in his autobiography.)

In 1933 the situation was changed by the Nazi revolution in Germany. Kubelka refused to go to Germany and had few choices in the rest of Central Europe, so he returned to technological contributions – soon founding the company Kubelka Schuloff & Co., which eventually changed to Dr. P. Kubelka & Co. The company established a research laboratory and later a small factory. Products such as the fungicide Cuprenox were successful. References [6] and [7] are two representative patents from that era. But World War II disturbed this success and prevented the realization of other inventions. Furthermore, Kubelka was forced to change to German citizenship and then was ostracized by the Nazis.

During the postwar events of 1945, Kubelka and his wife were interned by mistake. His wife died in the camp, and he was released finally by the efforts of Czech and Jewish friends in September 1945. His German citizenship was

nullified, he was promised to regain Czechoslovak citizenship, and he accepted a position as a research chemist at the Film Company at Cesky Brod near Prague, branch factory of the Aussig Combine (SPOLCHEMIE). There he worked out a new photomechanical emulsion and reorganized the testing system. Upon deciding to go to America, he was told that the Czech authorities intended to prevent him as a specialist from leaving the country. The only place to emigrate legally was to Germany. Through the date of writing of his autobiography, he then lived in Bavaria with his children, working on the optical theory of light-scattering materials and thermodynamics of absorption and capillary condensation. In March 1947 he married Dr. Brigitte Gade.

After emigrating to Brazil in 1950, Paul Kubelka conducted further research to generalize his optical transfer theory to inhomogeneous layers [3]. He passed away in 1954 in Rio de Janeiro, where he was head of the Research Laboratory at the Brazilian Ministry of Agriculture.

Lambert, Johann Heinrich

Rolf G. Kuehni
NCCharlotte, USA

Biography

Lambert was born on August 26, 1728 in the city of Mulhouse, then an enclave of Switzerland (now part of France). He was largely self-educated, going to school only until age 12. By age 17 he assumed the job of secretary to a newspaper publisher in nearby Basel, Switzerland. He also began to work as a private tutor. At age 20 he became tutor to three boys in the family of Count Peter von Salis in Chur, Switzerland, a position he held for 10 years. There he had access to the count's large library and was able to travel widely in Europe with his charges. In 1755 he began to

publish scientific articles on a number of subjects. In 1756 he traveled with his pupils to Göttingen in Germany where he met Tobias Mayer and was elected a member of the *Königliche Gesellschaft der Wissenschaften* (Royal Society for the Sciences). In 1759 he published his work on light measurement, *Photometria* [1], introducing his mathematical formula for the law of absorption of light (Lambert's law), described non-mathematically a few years earlier by Pierre Bouguer. In 1764 he followed an invitation by the Swiss mathematician Leonhard Euler to come to Berlin where, after some initial difficulties, Frederic II appointed him to a position in the *Königlich-Preussische Akademie der Wissenschaften* (Royal Prussian Academy of Sciences). Lambert established an important position as mathematician, physicist, astronomer, and philosopher. He also had considerable interest in the art of painting. Among many other achievements, Lambert was the first to mathematically prove the irrationality of the number π . He died on September 25, 1777 in Berlin, Germany [2].

Major Accomplishments/Contributions

In 1758 Tobias Mayer presented his public lecture on a three-dimensional color order system, of which a report was published in *Göttingische Anzeigen für gelehrte Sachen* (Göttingen reports on learned matters), read by Lambert. In 1768 Lambert published an article *Mémoire sur la partie*

Lambert, Johann Heinrich, Fig. 1 Lambert's illustration of his triangular color pyramid, 1772

photométrique de l'art du peintre (Dissertation on the photometric component of the art of the painter) [3] in which he discussed the effect of light on the appearance of colored materials. Soon after and as a result of Mayer's premature death, he began work on an implementation of Mayer's conceptual double pyramidal system, with assistance of the Prussian court painter Benjamin Calau (1724–1785). The result was published in 1772 as *Beschreibung einer mit Calauischem Wachse ausgeführten Farbenpyramide* (Description of a color pyramid painted with Calau's wax) [4] containing a hand-colored abbreviated version of the conceptual color pyramid (Fig. 1) [3]. Lambert and Calau had to solve a number of practical issues, for example, they determined the relative strength of the pigments they used. When mixing the three primary paint samples, they obtained near-black colors. As a result, Lambert saw no need for the lower half of Mayer's double pyramid. The Lambert-Calau pyramid is the first three-dimensional illustrated representation of a systematically developed color solid.

Synonyms

Lanthanide ions; Lanthanides; Rare earth elements; Rare earth ions; Rare earths

Definition

The lanthanoids (often designated Ln) are the 15 elements with atomic numbers 57 (lanthanum) to 71 (lutetium).

Colors, Electron Configurations, and Energy Levels

Color

Most of the lanthanoid ions exhibit rather pale characteristic colors when introduced into transparent solids or in water solutions: the most important being the Ln^{3+} state (Table 1). These colors arise from electronic transitions between the ionic ground state and energy levels derived from 4f electron configurations lying between 1.77 eV and 3.10 eV above it, giving absorption

maxima in the visible wavelength range (700–400 nm). Of more practical importance is color produced when ions excited to higher energy levels fall back to these 4f-derived levels and thence to the ground state, giving rise to characteristic visible emission spectra, which are used in many applications including fluorescent printing inks used as security markers on banknotes.

The 4f electrons in the lanthanoids are well shielded beneath an outer electron configuration ($5s^2\ 5p^6\ 6s^2$) and so are little influenced by the surrounding solid matrix, and although crystal-field effects (see ► “Transition Metal Ion Colors”) contribute to the fine structure of the electronic spectra of the lanthanoid ions, these do not have a gross effect upon the color. This implies that the most important optical properties attributed to the 4f electrons on any particular lanthanoid ion do not (usually) depend significantly upon the host structure, so that lanthanoid elements find use in phosphors, lasers, and other light-emitting devices, where a host lattice can be chosen with respect to processing conditions without significantly changing the desirable color properties of the ion.

Lanthanoid Ion Color, Table 1 Characteristic color of lanthanoid ions

Element	Ion ^a	4f occupancy ^b	Color
Lanthanum	La^{3+}	$4f^0$	Colorless
Cerium	Ce^{4+}	$4f^0$	Colorless
	Ce^{3+}	$4f^1$	Pale yellow
Praseodymium	Pr^{4+}	$4f^1$	Colorless
	Pr^{3+}	$4f^2$	Green
Neodymium	Nd^{3+}	$4f^3$	Lilac/violet
Promethium	Pm^{3+}	$4f^4$	Pink
Samarium	Sm^{3+}	$4f^5$	Pale yellow
	Sm^{2+}	$4f^6$	Red/green
Europium	Eu^{3+}	$4f^6$	Pink
	Eu^{2+}	$4f^7$	Red-brown
Gadolinium	Gd^{3+}	$4f^7$	Colorless
Terbium	Tb^{4+}	$4f^7$	Colorless
	Tb^{3+}	$4f^8$	Pale pink
Dysprosium	Dy^{3+}	$4f^9$	Pale yellow
	Dy^{2+}	$4f^{10}$	Brown
Holmium	Ho^{3+}	$4f^{10}$	Yellow
Erbium	Er^{3+}	$4f^{11}$	Pink
Thulium	Tm^{3+}	$4f^{12}$	Green
	Tm^{2+}	$4f^{13}$	Green
Ytterbium	Yb^{3+}	$4f^{13}$	Colorless
	Yb^{4+}	$4f^{14}$	Colorless
Lutetium	Lu^{3+}	$4f^{14}$	Colorless

^a Ln^{3+} is the principal ionic state encountered
^bThere is uncertainty about the exact f-orbital occupation in many compounds

Lanthanoid Free-Ion Energy Levels

The energy levels of a free lanthanoid ion are usually labeled with atomic *term symbols* derived by *Russell-Saunders (LS) coupling* (although other coupling schemes are also used in this respect). A *term* is a set of states which are very similar in energy, and the appropriate term symbol is written as ^{2S+1}L where L is a many-electron quantum number describing the total orbital angular momentum of all of the electrons surrounding the atomic nucleus and S is a many-electron quantum number representing the total electron spin. The superscript ($2S + 1$) is called the *multiplicity* of the term and is given a name: 1, singlet; 2, doublet; 3, triplet; 4, quartet; and so on. The total angular momentum quantum number L is given a letter symbol: $L = 0$, S; $L = 1$, P; $L = 2$, D; $L = 3$, F; and thereafter alphabetically, omitting J. The energies of the terms must be determined by quantum mechanical calculations, except for that of the ground state, which is given by Hund’s second

rule: the ground state is the term with the highest multiplicity and, if more than one term of the same multiplicity is present, by that with the highest L value.

The term symbol does not account for the true complexity of the energy levels of the lanthanoid ions. This arises from the interaction between the spin, S , and the orbital momentum, L , called *spin-orbit coupling*. For this the quantum number, J , is needed. It is given by:

$$J = (L + S), (L + S - 1) \dots |L - S|$$

where $|L - S|$ is the modulus (absolute value) of the quantity $L - S$. Each value of J represents a different energy level. The new quantum number is incorporated as a subscript to the term, now written $^{2S+1}L_J$ and called a *level*. It is found that a singlet term always gives rise to one level, a doublet two, a triplet three, and so on (Table 2). The energies of these levels can be sorted in terms of energy by Hund's third rule: the level with the lowest energy is that with the lowest J value if the valence shell is up to half full and that with the highest J value if more than half full. The separation between the components of the spin-orbit energy levels is of the order of 0.1–0.25 eV. (For

comparison, crystal-field splitting of these energy levels, which is due to the interaction of the f orbitals with the surrounding atoms in a solid or liquid, is about 0.01 eV.)

In the presence of a magnetic field, the spin-orbit levels are split further due to the Zeeman effect. The same is true of static electric fields, where it is called the Stark effect. In both cases, atoms or ions in a gas or free space will show an average effect because of the motion of the particles. However, in a crystal the atom and ion positions are more or less fixed, and the application of either magnetic or electric fields along certain symmetry directions will, in general, cause different degrees of splitting of the levels than the same fields applied along other symmetry directions. Zeeman splitting has been used to change the optical properties of lanthanoid ions in optomagnetic materials.

Selection Rules

Electron transitions are governed by selection rules that give the *probability* that the transition will occur. Transitions between energy levels derived purely from f orbitals are forbidden by the Laporte selection rule. However, this rule may break down for ions in compounds. The main reason for this is a degree of mixing between s , p , d , and f orbitals can occur when an ion is not located at a center of symmetry. As s , p , or d to f transitions are allowed, transitions giving rise to color are also allowed, to a degree corresponding to the amount of orbital mixing achieved. In addition, transitions are only allowed between states of the same multiplicity, called *spin-allowed transitions*. Transitions between states of differing spin can be weakly allowed and in some circumstances can also contribute to observed lanthanoid color. The weak colors exhibited by Ln^{3+} ions are primarily due to these restrictions, especially when compared to typical crystal-field colors of the 3d transition-metal ions (see ► “Transition Metal Ion Colors”).

Some Lanthanoid Absorption Colors

The $4f^0$ ions La^{3+} and Ce^{4+} and f^{14} ions Yb^{4+} and Lu^{3+} have no f – f energy levels and are colorless.

$\text{Lu}^{3+} f^{14}$	^1S	$^1\text{S}_0$

^aIn ascending energy order, ground state level **bold**

The colorless ions Gd^{3+} and Tb^{4+} have a stable $4f^7$ configuration, and there are no energy levels in the appropriate energy range to give rise to color. The same is true for the $4f^{13}$ ion Yb^{3+} .

Ce^{3+} and Eu^{2+}

The lowest energy levels of Ce^{3+} , arising from the single f electron, are $^2F_{7/2}$ and $^2F_{5/2}$. The next higher energy state for Ce^{3+} is the 5d level. Due to the interaction of the more exposed 5d electrons with the surrounding crystal structure, this is broadened into a band of energies, which also may overlap with another broadened band of energies derived from the 6s energy level (Fig. 1a). Transitions between the 5d band and 4f levels are allowed, and the colors produced by transitions of this type are intense. This transition absorbs at the violet end of the spectrum, and the absorption band often encroaches into the visible with a consequence that to the eye Ce^{3+} compounds are perceived as pale yellow.

Eu^{2+} , with a configuration $4f^7$, also has a simple energy level diagram because the energy of the state obtained by transferring an f electron to the outer 5d orbitals is lower than the other 4f energy levels (Fig. 1b). As in the case of Ce^{3+} , transitions from the ground state to the upper energy band are allowed. The energy gap is slightly smaller than in the case of Ce^{3+} , and so the absorption moves slightly deeper into the visible spectrum. Because of this, the color of Eu^{2+} compounds is described as red-brown.

Note that as the d orbitals interact strongly with the surrounding anions, the exact position of the band depends upon the host crystal. Thus, the colors of Ce^{3+} and Eu^{2+} compounds, unusually for lanthanoid ions, vary with host structure.

Pr^{3+} , Tm^{3+} , Nd^{3+} , and Dy^{3+}

The presence of Pr^{3+} ions generally colors the host matrix green. The principal transitions that contribute to the absorption spectrum are from the ground state 3H_4 to 3P_0 , at approximately

L

Lanthanoid Ion Color,
Fig. 1 Energy level diagrams (schematic) for (a) Ce^{3+} and (b) Eu^{2+} ions

Lanthanoid Ion Color, Fig. 2 Energy level diagrams (schematic) for (a) Pr^{3+} , (b) Tm^{3+} , (c) Nd^{3+} , and (d) Dy^{3+}

485 nm (blue-green), to $^3\text{P}_1$ at approximately 470 nm (blue) and to $^3\text{P}_2$ at approximately 450 nm (blue). A weak spin-forbidden transition to $^1\text{D}_2$ at approximately 590 nm (orange) is also present. Between these absorption peaks is a window of low absorption in the green region of the spectrum (Fig. 2a). The other “green” ion is Tm^{3+} . Here the main transitions are from the ground state $^3\text{H}_6$ to $^3\text{F}_3$ at approximately 690 nm (red), to $^3\text{F}_2$ at approximately 665 nm (red), and a weak spin-forbidden transition to $^1\text{G}_4$ at approximately 465 nm (blue) (Fig. 2b). Between these absorption bands is a green transmission window similar to that for Pr^{3+} . The Nd^{3+} ion tends to impart a lilac hue to materials. The main transition here is from the ground state $^4\text{I}_{9/2}$ to $^4\text{G}_{5/2}$ level, which absorbs strongly at approximately 585 nm (yellow), together with a transition to $^4\text{G}_{7/2}$ at approximately 525 nm (green) and $^2\text{G}_{9/2}$ at 510 nm (blue-green) (Fig. 2c). These absorption peaks remove the middle part of the optical spectrum, leaving both the violet and red extremes, so imparting a lilac hue to compounds. In the case

of Dy^{3+} with an electron configuration $4f^9$, there are two major absorption transitions, from the ground state $^6\text{H}_{15/2}$ to $^4\text{F}_{9/2}$ absorbing at 483 nm and to $^4\text{I}_{15/2}$, absorbing at 477 nm (Fig. 2d). Both of these remove blue from the spectrum, leaving materials containing Dy^{3+} to show a yellow coloration.

Some Applications of Lanthanoid Fluorescence Colors

Trichromatic Fluorescent Lamps

Trichromatic (color 80) fluorescent lamps use phosphors with active lanthanoid ions. Generally the lanthanoid ions can absorb a wide range of ultraviolet radiation efficiently, exciting the ions from the 4f-derived ground state to a broad band of energies formed from the interaction of 5d and 6s bands. Energy is then lost internally, in effect causing the phosphor matrix to warm slightly, until the sharp 4f-derived energy levels are reached. Photon emission between these energy

levels then occurs, giving color output. The favored red emitter is Eu^{3+} doped into Y_2O_3 ($\text{Y}_2\text{O}_3:\text{Eu}$), with the Eu^{3+} ions occupying the Y^{3+} sites. The ground state of Eu^{3+} is ${}^7\text{F}_0$. A transition from this state to the higher energy band, 5d band, absorbs the ultraviolet radiation given off by excited mercury atoms at 254 nm. Subsequent internal energy loss leaves the ion in the ${}^5\text{D}_0$ level. The main optical transition is between this level and ${}^7\text{F}_2$, producing emission at 611 nm (Fig. 3a). The green emission is from Tb^{3+} in host matrices $\text{La}(\text{Ce})\text{PO}_4$, $\text{LaMg}(\text{Ce})\text{Al}_{11}\text{O}_{19}$, or $\text{La}(\text{Ce})\text{MgB}_5\text{O}_{10}$, in which the Tb^{3+} ions replace La^{3+} . Tb^{3+} absorbs the mercury emission poorly, so it is coupled with a sensitizer, usually Ce^{3+} , which is able to absorb the 254-nm-wavelength mercury radiation efficiently by way of the 5d band. This absorbed energy is then transferred to the Tb^{3+} ions. The green emission, at a wavelength close to 540 nm, is mainly from a ${}^5\text{D}_4 \rightarrow {}^7\text{F}_5$ transition (Fig. 3b). Three other peaks of lesser intensity occur: ${}^5\text{D}_4 \rightarrow {}^7\text{F}_6$, 489 nm; ${}^5\text{D}_4 \rightarrow {}^7\text{F}_4$, 589 nm; ${}^5\text{D}_4 \rightarrow {}^7\text{F}_3$, 623 nm. The blue emission is produced by Eu^{2+} ions. The excitation and emission is directly to and from the 5d-derived band. The position of this band is strongly influenced by the host structure, and the usual tricolor lamp phosphor, $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}$, is chosen so as to have a suitable blue emission, with a maximum at 450 nm (Fig. 3c).

Plasma Displays

Plasma display panels are made up of a pair of glass plates containing a series of cells each of which acts as a miniature fluorescent lamp as described above. Each lamp is several hundred microns in size, and there are several million such lamps in a display. Each pixel consists of three lamps, giving off red, blue, and green lights. The working gas in the cells is a mixture of helium and xenon. When a high voltage is applied across two electrodes above and below a well, the gas is excited into a state that emits ultraviolet radiation, with principal wavelengths of 147 nm and 172 nm. Each well is coated internally with a red, green, or blue phosphor. The main lanthanoid phosphors used at present are yttrium gadolinium borate doped with europium ($\text{Y,Gd}\text{BO}_3:\text{Eu}^{3+}$, which gives a red emission, and barium magnesium aluminate doped with europium, $\text{BaMgAl}_{14}\text{O}_{23}:\text{Eu}^{2+}$, for blue emission (see Fig. 3). The green emission utilizes Mn^{2+} rather than a lanthanoid ion.

Phosphor Electroluminescent Displays

Electroluminescent displays containing a thin film of a phosphor, called thin-film electroluminescent (TFEL) displays, find use as flat panel color displays and backlighting in products such as instrument panels. The most promising devices use *ac* supplies in a thin-film electroluminescent (ACTFEL) display. Under the influence of an applied electric field, electrons enter the phosphor

Lanthanoid Ion Color,

Fig. 3 Energy level diagrams (schematic) for (a) Eu^{3+} , (b) $\text{Ce}^{3+}/\text{Tb}^{3+}$, and (c) Eu^{2+} in trichromatic lamp phosphors. ET energy transfer

Lanthanoid Ion Color, Fig. 4 Energy level diagrams (schematic) for (a) Eu^{2+} , (b) Tb^{3+} , and (c) Ce^{3+} in AC-powered thin-film electroluminescent (ACTFEL) displays

at the junction with a surface insulating coating. These are accelerated under the influence of the field until they collide with the luminescent centers in the phosphor, transferring energy in the process. The excited luminescent centers then fall back to the ground state and release energy by light emission.

Red emission is from calcium sulfide doped with europium ($\text{CaS}:\text{Eu}^{2+}$); the color is being generated by the transition from the 5d band to the ground state $^8\text{S}_{7/2}$ (Fig. 4a). At first sight this is surprising as the Eu^{2+} -derived tricolor lamp phosphor has a blue output. However, the position of the upper energy band depends upon the interaction of the d orbitals with the surrounding crystal, and in ZnS the softer bonding gives a broad emission centered close to 640 nm. Green emission is produced by zinc sulfide doped with terbium ($\text{ZnS}:\text{Tb}^{2+}$), with an output at a wavelength close to 545 nm, mainly from a $^5\text{D}_4 \rightarrow ^7\text{F}_5$ transition (Fig. 4b). Three other peaks of lesser intensity occur: $^5\text{D}_4 \rightarrow ^7\text{F}_6$, 489 nm; $^5\text{D}_4 \rightarrow ^7\text{F}_4$, 589 nm; $^5\text{D}_4 \rightarrow ^7\text{F}_3$, 623 nm. Blue emission still poses a problem for these displays, but the thiogallates CaSr_2S_4 , SrGa_2S_4 , and BaGa_2S_4 doped with the $4f^1$ ion Ce^{3+} are currently favored. The transitions between the 5d band and the $4f^1$ ground state doublet $^2\text{F}_{5/2}$ and $^2\text{F}_{7/2}$ are both in the blue region of the spectrum centered at 459 nm for the Ca

compound and 445 nm for the Sr and Ba phases (Fig. 4c).

Upconversion

The conversion of infrared radiation to visible is variously known as upconversion, frequency upconversion, anti-Stokes fluorescence or cooperative luminescence. The majority of studies of upconversion have involved the lanthanoid ions Er^{3+} , Tm^{3+} , Ho^{3+} , and Yb^{3+} . At present the most efficient upconversion materials for infrared to visible conversion are lanthanoid fluorides such as NaLnF_4 doped with $\text{Yb}^{3+}/\text{Er}^{3+}$ or $\text{Yb}^{3+}/\text{Tm}^{3+}$ couples. The energy for upconversion can be gained by the active ion via several competing energy transfer processes. In principle, the simplest is for the active ion to pick up photons in two distinct steps. The first photon excites the ion from the ground state to an excited energy level, a process referred to as *ground state absorption* (GSA). A subsequent photon is then absorbed to further promote the excited ion to a higher energy level again, a process referred to as *excited state absorption* (ESA). The oxide CeO_2 doped with approximately 1% Er^{3+} exhibits upconversion in this way. Irradiation with near-infrared photons with a wavelength close to 785 nm excites the Er^{3+} ions from the $^4\text{I}_{15/2}$ ground state to the $^4\text{I}_{9/2}$ level:

Subsequent internal energy loss drops the energy to the $^4\text{I}_{11/2}$ and $^4\text{I}_{13/2}$ levels (Fig. 5a). The ions are then excited by ESA. Those in the $^4\text{I}_{11/2}$ energy level are excited to the $^4\text{F}_{3/2, 5/2}$ doublet:

These states subsequently relax to the $^2\text{H}_{11/2}$, $^4\text{S}_{3/2}$, and $^4\text{F}_{9/2}$ levels (Fig. 5b):

The ions in the $^4\text{I}_{13/2}$ energy level follow a similar path, being excited to the $^2\text{H}_{11/2}$ energy level:

Lanthanoid Ion Color,

Fig. 5 Upconversion using Er^{3+} doped into CeO_2 , schematic:

- (a) GSA + relaxation,
(b) ESA + relaxation,
(c) ESA + relaxation, and
(d) light emission

and then subsequently relax to the $^4\text{S}_{3/2}$ and $^4\text{F}_{9/2}$ levels (Fig. 5c):

The result of this is that the levels $^2\text{H}_{11/2}$, $^4\text{S}_{3/2}$, and $^4\text{F}_{9/2}$ are populated to varying degrees, depending upon the precise details of the excitation and relaxation steps. Subsequent loss of energy from these levels gives rise to green and red emissions (Fig. 5d):

All upconversion spectra from Er^{3+} (including those using different mechanisms) are similar, but the relative intensities of the three peaks vary with concentration of the ions and the nature of the host matrix.

Energy transfer, in which input radiation is picked up by a sensitizer and is then passed to the emitter, is the mechanism of operation of host structures containing the co-dopants $\text{Yb}^{3+}/\text{Er}^{3+}$, which give a strong green emission, and $\text{Yb}^{3+}/\text{Tm}^{3+}$ which gives a blue emission. The ion that absorbs the incoming infrared radiation is the Yb^{3+} ion, which then transfers energy to Er^{3+} or

Lanthanoid Ion Color, Fig. 6 Visible light emission (quantum cutting) via photon cascade emission from Pr^{3+} ions irradiated by ultraviolet light

Tm³⁺ centers. Other upconversion mechanisms are also known.

Quantum Cutting

Quantum cutting is the reverse of upconversion, as one high-energy photon is processed (i.e., cut) to give out several lower-energy photons, typically transforming ultraviolet to visible. There are several mechanisms for quantum cutting; here photon cascade emission, exhibited by Pr³⁺ ions, is described. Initial absorption of high-energy 185-nm ultraviolet photons results in excitation to the 5d–6s energy band (Fig. 6). Subsequent relaxation takes the ion to the ¹S₀ level. Thereafter, the transitions giving rise to visible output are:

¹S₀ → ³P₃ at ~ 400 nm,
then ³P₀ → ³H₄ ground state at ~ 480 nm

¹S₀ → ¹D₂ at ~ 330 nm,
then ¹D₂ → ³H₄ ground state at ~ 605 nm

Other ions such as Tb³⁺ are also candidates for quantum cutting devices, but the mechanisms involved are more complex than that with Pr³⁺.

Le Blon, Jacob Christoph

Rolf G. Kuehni
Charlotte, NC, USA

J. C. Le Blon, Head of a woman, ca. 1720 (three-color printing process)

Biography

Le Blon was born on May 2, 1667 in Frankfurt am Main, Germany, a descendant of Huguenots fleeing France in 1576, having settled there. His grandmother was a daughter of the artist and engraver Matthaus Merian the Elder (1593–1650). Showing an early interest in engraving and painting, he had, sometime between 1696 and 1702, an extended stay in Rome where he is reported to have studied art under the painter and engraver Carlo Maratta

(1625–1713) [1]. Around 1702 Le Blon moved to Amsterdam, where he worked as a miniature painter and engraver. In 1708/1709 he is known to have made colorant mixing experiments in Amsterdam, and in 1710 he made his first color prints with yellow, red, and blue printing plates. In 1717 he moved to London where he received a royal patent for the three-color printing and a related textile weaving process [2]. In 1722 he published a small book on painting, *Coloritto*, in French and English [3]. There he stated that “Painting can represent all visible objects with three colors, yellow, red, and blue.” During his stay in England, he produced several dozen images printed from three or four plates (the fourth for black ink) in multiple copies that initially sold well in England and on the continent. In the long run his enterprise did not succeed, however. Le Blon left England in 1735, moving to Paris where he continued producing prints by his method. In 1740 he began work on a collection of anatomical prints for which he had a solid list of subscribers. He died on May 16, 1741 in Paris. A detailed technical description of Le Blon’s method was published in 1756 by Antoine Gautier de Montdorge who supported him during his final years in Paris [4].

Major Accomplishments/Contributions

The idea of three chromatic primaries, yellow, red, and blue, was quite well established in Le Blon’s time among painters, graphically represented by Aguilonius in 1613 [5] and described by R. Boyle in 1664 (p. 220) [6]. What was new in Le Blon’s work is that he applied this concept to color printing of images in an entirely new fashion making greater and much subtler detailing and coloration possible. It required experience in deconstructing an image in terms of color so that printing multiple copies, based on only three or four plates, produced good quality coloration. It required the ability to mentally resolve the image into its presumed primary chromatic components and understanding and predicting the effects of superimposed printing inks in certain areas, for which extensive trial and error work was required. Le Blon manually engraved copperplates, using the mezzotint process, with the relative components of the three primary colors printed

successively in registration in the sequence blue, yellow, and red onto the paper substrate. As he gained experience, he at times used a fourth plate printing in black to achieve greater tonality and contrast, thus employing an early version of the CMYK process. Le Blon used the pigments Prussian blue, Stil de grain (yellow lake), a mixture of red lake and carmine for red, and a common printer’s black ink [4]. The pigments were dispersed in copal tree resin dissolved in copal oil to make the inks. The technical problems associated with the process prevented it from becoming a standard method and lithographic printing of color images from up to a dozen wood engravings or stones per image continued until H. E. Ives’ invention of the chromatic halftone printing process ca. 1890.

Light Distribution

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

Luminous intensity distribution

Definition

A luminaire property that indicates the values of the luminous intensities radiated in all relevant directions by the luminaire. Usually, the luminous intensities are given as intensities per 1000 lamp lumen when the lamp or lamps are operated under standard test conditions: 1/1000 lm.

Luminaire Performance Characteristic

The light distribution of a luminaire represents the most important performance characteristic of a luminaire. It is the basis for the determination of photometric characteristics of luminaires such as upward and downward light output ratio, utilization factors for defined areas or zones, beam angles, and glare figures. Luminaire manufacturers produce for their luminaires photometric datasheets which show these photometric characteristics together with a graphical representation of the light distribution itself.

Measurement

Strictly speaking, the light distribution can only be measured for a point source. In practice, the

measurement inaccuracy will be negligible provided the optical path length of the measuring setup is at least ten times the length of the light-emitting surface of the luminaire. For narrow beam projector type of luminaires, greater optical path lengths are required. The instrument used for measuring light distributions is called a goniophotometer. It exists of a mounting support for the luminaire, a photocell, and a, usually complex, system that rotates the combination of photocell and luminaire such that the intensities from all different light directions can be measured. Mirrors are used to keep the actual dimensions as small as possible while keeping the required optical path length. It is essential that the luminaire rotates in such a way that its normal operating position is at all times maintained. The measurements should be carried out under standard test conditions. These conditions refer to ambient temperature, air movement, mounting position, and lamp ballast type. The coordinating systems used for indicating the directions are either the so-called B-beta (usually used for projector type of luminaires) or the C-gamma system. The B angles of the B-beta system can be understood as the angles the pages of a book make when the book axis is held horizontally. The beta angles are angles in each page measured from the middle of the book axis. The C-gamma system in the same analogy can be understood as a book with its axis held vertically. C angles are the angles the pages make, and gamma angles are angles in the pages from the middle of the book axis.

Graphical Presentation

For the selection of suitable luminaires for a particular application, clear insight into the photometric quality of a luminaire is needed. This is why luminaire manufacturers produce photometric datasheets containing at least the polar intensity diagram. The polar luminous intensity diagram provides a good indication of the suitability of the light distribution for a certain application. In such diagram, the luminous intensities are presented using the C- γ system of coordinates in the form of curves in terms of cd/1000 lm of the

Light Distribution,
Fig. 1 Light distribution in the form of the polar luminous intensity diagram of the luminaire for which the I-table is given in Table 1

nominal lamp flux of the lamps employed (Fig. 1). Each curve represents one C plane. Curves are given for only the more important planes. For indoor lighting luminaires that are at least the planes through the two main axes of the luminaire. Rotationally symmetrical luminaires have the same light distribution in all C planes. The example of Fig. 1 shows a polar luminous intensity diagram of an indoor lighting luminaire that radiates its light in both the downward and upward direction. In the downward direction, it has a directional component in the plane across the longitudinal luminaire axis (C0–180° plane; red curve) and a rather diffuse component in the direction parallel to the longitudinal luminaire axis (C90–270°; blue curve). The upward component is diffuse in all planes which is the reason that the red and blue curves coincide.

Intensity Table

All lighting calculations of lighting installations are based on the light distribution of the

luminaires used. For this purpose the light distribution is given as a two-dimensional table, the so-called I-table. There are some different formats for these I-tables such as CIE, IESNA, Eulumdat, CIBSE, and some luminaire manufacturer’s specific formats. Eulumdat is the most popular format in Europe, whereas the IESNA format is more popular in the USA. The CIE format is an attempt to define a “recommended file format for electronic transfer of luminaire photometric data” on a global level, in order to overcome the regionally different formats currently in use. Many light calculation programs can use some different formats as input. Moreover, free software for conversion from one format to the other is available as well. The layout of the I-table is different for different types of luminaires. So have road lighting luminaire I-tables more values around the direction of the horizon than for other directions because these values very much determine glare, general lighting interior luminaire I-tables have a somewhat more regular layout because of the more diffuse character of these luminaires, and flood and accent lighting luminaires (projector type of luminaires)

Light Distribution, Table 1 I-table with the luminous intensity values for a specific luminaire (values are in cd/1000 lm)

Gamma	C0°	C15°	C30°	C45°	C60°	C75°	C90°
0°	322	322	322	322	322	322	322
10°	319	319	319	319	319	319	319
20°	313	312	311	309	306	304	302
30°	320	317	308	297	287	281	279
40°	352	345	326	301	269	245	234
50°	140	145	154	139	137	126	123
60°	66	66	66	68	65	63	62
70°	38	35	35	36	35	36	39
80°	19	20	22	22	22	19	19
90°	2.2	2.2	2.1	1.8	1.5	1.1	0.9
100°	6.1	6.1	6.2	6.2	6.1	5.9	5.8
110°	12	12	12	12	13	13	13
120°	22	22	22	23	23	24	24
130°	40	40	40	40	41	41	42
140°	60	60	60	60	60	61	61
150°	76	75	76	75	75	75	76
160°	84	84	84	84	84	85	85
170°	89	89	89	89	90	90	90
180°	91	91	91	91	91	91	91

have I-tables with extra values around the direction of the maximum beam intensity.

Table 1 shows part of an I-table in the C- γ coordinate system. The intensity tables usually give relative intensity values, viz., candela/1000 lamp lumen values to make the values solely dependent on the luminaire and not on the actual lumen of the lamp. For LED luminaires with non-replaceable LEDs, the intensity tables are usually given for the actual lumen that the luminaire emits. The luminaire used for the example of Table 1 is symmetrical relative to the C90–270° plane. For luminaires that do not have such symmetry, the intensity values for the planes C90 to C180° must also be given. Intensity tables used as input for calculation software have to be specified with smaller steps between the gamma and C angles.

Light Pollution

Terry McGowan
Lighting Ideas, Inc, Cleveland Heights, OH, USA

Synonyms

[Glare](#); [Sky glow](#); Unwanted light especially referring to unwanted electric lighting at night

Definition

Outdoor electric lighting at night which is unwanted, unneeded, or wasteful and which results in glare, light trespass and sky glow or other harmful effects on people and the environment.

Light Pollution Recognized

Electric lighting makes travel, working, playing, and other normal living activities possible at

night. Indeed, the view of a lighted city from an airplane window or tall building is a hallmark of twenty-first-century civilization, yet little more than a century and a half ago, there were no such views and human activities outdoors at night were limited to those considered essential. Even then, they were carried out only with difficulty especially tasks involving work or travel. Limitations remained as candles and then gas flames and mantles began to generate more powerful and reliable night lighting, but the benefits were not widespread because of the relatively high cost of providing light especially over large outdoor areas at night.

When electric lighting was invented, one of its first uses was for outdoor illumination. Carbon arc lamps were used initially and then incandescent light sources, which were developed during the 1870s. These became the worldwide standard for all types of lighting until the commercial introduction of the fluorescent lamp in the late 1930s. Outdoor lighting, however, did not dramatically change until mercury lamps, the first of the so-called high-intensity discharge (HID) lamps became widely used for street, parking, and area lighting during the 1960s and then other types of HID lamps – high-pressure sodium (HPS) and metal halide (MH), due to their relatively higher efficacies, transformed the cost and use of outdoor lighting leading to rapid growth and the night time appearance of cities that we see today. Now, however, a new transformation is underway characterized by the growing use of solid state lighting in the form of Light Emitting Diodes (LEDs) which are increasingly being used for outdoor lighting.

Electric lighting has changed the night. And there are negative aspects that were recognized early on by critics who pointed out that bright lights frightened horses, annoyed pedestrians, and produced glare. There were those who also noticed that electric light changed the egg-laying habits of chickens, attracted insects, and modified the leaf and flowering characteristics of certain plants – early examples that hinted at more significant problems that later appeared due to unneeded or unwanted light. But the term “light pollution” did not appear until much later – in the 1980s. That’s when the large, powerful HID

lamps began to be used in large quantities for major outdoor lighting systems such as street lighting, parking areas, signs, sports stadiums, and floodlighting. The stray, uncontrolled light from these new sources as typically used outdoors plus the light from the headlights of cars and light escaping through windows from the interior lighting systems of buildings at night has now transformed the night environment in conspicuous ways including making the night sky less visible. Instead, light into the sky blankets cities with “sky glow,” a fog, or haze of light.

Astronomers, both professional and amateur, were among the first to recognize and talk about sky glow as light pollution as they tried to observe the stars from urban locations. As a first response, professional astronomers moved telescopes and observatories from cities to new locations in remote areas. Then, it was recognized that such places were increasingly rare and costly to develop. Further, most amateur astronomers were not able to move or take advantage of such sites. Members of the public who simply wanted to catch a glimpse of the Milky Way from their backyard or to show their children a comet or star constellation were not able to do so. The result is a growing and widespread reaction to uncontrolled electric lighting outdoors at night.

Efforts began, usually via zoning, planning, or the so-called “nuisance” regulations to limit and control unwanted light especially around astronomical observatories. It was found that light from urban areas could significantly affect the sky brightness 100–200 km away and that minimizing light directed into the sky was a simple and effective way to control such light. The term “light pollution” became familiar and efforts began to understand the various associated problems and to find ways to limit the detrimental effects. A global organization, the International Dark Sky Association (IDA), founded in 1988, focused on the task and continues to work “to preserve and protect the nighttime environment . . . through environmentally responsible outdoor lighting” [1]. Other regional and local organizations also appeared worldwide to raise awareness of the problems, write laws, provide educational materials, and organize local activities such as promoting the

use of shielded luminaires. Lighting technical and professional organizations have also recognized light pollution problems and have sponsored research, issued reports, produced recommended lighting practices, and written model legislation [2–4] in order to control it.

Types of Light Pollution

Light pollution was initially understood as primarily a visual problem caused by unnecessary or uncontrolled outdoor lighting that interfered with the viewing of the sky. But, there are now other considerations, and light pollution has been more broadly defined and classified as follows:

- **Light trespass** – Light generated in one location which, when poorly controlled, travels to another location where it is not wanted. An example would be a streetlight which is intended to light the street surface but also directs light into front yards or bedroom windows along the street.
- **Glare** – Excessive light directed into the eye where it causes visual discomfort or reduces the ability to see. Overly bright unshielded or misaimed luminaires are usually the main sources of glare.
- **Sky glow** – Light directed or reflected into the sky where it is scattered by air molecules, water, and other particles in the atmosphere and reflected diffusely to produce a fog or haze of brightness that reduces the visibility of the night sky.

Light pollution has energy implications since stray or misdirected light is luminous energy which has been converted from electric energy by the light source. That electric energy, the fuel, and other resources which produce it have therefore been wasted, delivering no value to those who pay for those resources.

The IDA estimates that some 30% of the electric energy used for outdoor lighting goes into the sky. Considering the hours of operation and an average electrical energy rate of \$0.10/kWh

(USA), the cost of that wasted energy is well over \$2 billion/year.

Spectral Effects

Electric lighting is the cause of light pollution. However, all light sources are not equally effective at generating light pollution of the types described. The scattering of light in the atmosphere that affects sky glow, for example, is a function of the wavelength of the light (Rayleigh scattering). Such scattering affects how far light pollution will travel. Similarly, the intensity (candlepower) of the luminaire as well as the way the light is aimed and directed matters too.

Astronomers who first sought to alleviate sky glow during the 1970s and 1980s found that the light from low-pressure sodium (LPS) lamps was helpful because all of the light from such lamps is emitted in a narrow range of wavelengths in the yellow part of the spectrum. A telescope equipped with a filter that absorbed those wavelengths and transmitted the rest of the spectrum would therefore see the sky as “dark.” US cities such as Tucson, AZ, and San Jose, CA, installed LPS street and area lighting as a way to maintain dark skies for area observatories while still providing essential lighting for drivers and pedestrians. LPS lamps, however, have poor color rendering and so there were objections to the light. Provisions were made for exceptions so that white light could be used in such applications as outdoor automobile sales lighting and sports facilities. Installations permitted as exceptions usually had other conditions attached that limited total lighting wattage, mandated certain operating hours, or required shielding – often in combinations. Of course, for the amateur astronomer or the casual viewer of the sky, outdoor lighting with LPS lamps and luminaires, which are typically unshielded, offers no advantage since the yellow light is visible to the eye and continues to produce light pollution via glare, light trespass, and sky glow (Fig. 1).

Note that while the spectral characteristics of the light source matter, overall light pollution, including sky glow, is the result of not only how

Light Pollution, Fig. 1 Example of the effect of light pollution on the visibility of the sky in a residential area near Toronto, Ontario, Canada. *Left:* during an area-wide power failure stars and constellations can be clearly seen.

Right: the same view after the power had been restored with streetlights, floodlights, and other outdoor lighting contributing to sky glow

L

the light is generated but also how it is modified by outdoor surfaces via reflection, refraction, and absorption. However, light pollution which interferes with a view of the sky in any given situation is always directly proportional to one quantity: total luminous power. Measured in lumens, luminous power is radiant power modified by the spectral sensitivity of the human eye. The key to controlling light pollution is to limit or reduce the total lumens being generated from light sources and sent into the night environment. Turning lights off when not needed, shielding luminaires, and reducing illumination levels to the minimum values required are all techniques that can be used to minimize light pollution problems. These are common-sense ideas, and there are many more [5, 6] although what should happen, of course, is that lighting should be designed to incorporate the long-established principles of proper lighting design which include the requirements to control stray light, minimize glare, and not use excessive light for the intended application. The problem is

that much outdoor lighting is not “designed” in the sense that major buildings are designed with careful thought given to materials, appearance, function, and purpose. Rather, outdoor lighting is often a make-do or do-it-yourself affair. It “happens” or factors of cost, expediency, or lack of information drive the installation (Fig. 2).

Other Light Pollution Effects

Research reported during the 1990s has shown that light pollution seriously affects the health and behavior of animals, including mammals, birds, amphibians, and insects. Changes in migration patterns, food gathering and feeding habits, mating, and social behavior have all been documented [7, 8]. However, bird and sea turtle problems have received the most attention.

Birds may become disorientated by lighting to the extent that they die from exhaustion while continuously circling lighted buildings or,

Light Pollution, Fig. 2

A comparison of the spectra of light sources commonly used for outdoor lighting.

Top: high-pressure sodium is the most widely used and is characterized by its familiar orange color.

Middle: metal halide lamps emit white light but can have a visually “warm” or “cool” color depending upon the chromaticity rating. Emissions, however, are relatively balanced over the visible spectrum.

Bottom: white-light LED light sources use blue-emitting LEDs to activate phosphors which emit the light shown in the 500 nm and above range. These so-called “blue-rich white-light” LEDs are of concern because light and human health research indicates that eye receptors which control circadian rhythms have a peak sensitivity near 460 nm, similar to the emission curve of the blue LEDs

confused, they collide with the buildings. According to a Chicago Audubon Society study [9] documented by actual counts of dead birds found at the base of tall buildings, bird deaths due to building collisions were reduced significantly when just the decorative floodlighting of buildings was switched off for most of the night hours during migration seasons.

Baby sea turtles hatch on beaches and have a short time to dig out of the sand and to find their way to the sea before they die by dehydration or are eaten by predators. The turtles appear to use the brightness of the horizon as a visual clue to find the water. Area and streetlighting along beachfront areas confuses the turtles, so efforts have been made to remove, turn off, or modify such systems including changing to amber-colored light sources which, because of their

spectral sensitivity, appear less bright to turtle eyes [10].

Human Health Effects

A controversial issue involving light pollution is whether or not outdoor lighting negatively affects human health. Research beginning in the 1970s has indicated that certain uses and kinds of electric light and, particularly, light at night (LAN) when the human body expects and needs darkness for sleep, can be detrimental to health because it interferes with the body’s normal circadian rhythms.

These rhythms mark the periods of alertness and sleep due to the ebb and flow of hormones, such as melatonin, in the body. According to the

research, strong circadian rhythms are essential for overall health and mental functioning and particularly for cell repair which helps protect against major diseases including cancer. The general rule is that people need bright days and dark nights so current research is exploring questions about light intensity, spectrum, timing, and exposure duration to determine the “dose” of light that might result in the interruption of the melatonin cycle and, further, what kind of interruptions lead to an increased risk of disease. The research literature on the subject is already extensive – one compilation now lists over 1,000 citations [11], and how outdoor lighting impacts human health will remain an important subject of research and discussion.

The American Medical Association adopted a resolution in 2009 entitled “Advocating and Support for Light Pollution Control Efforts and Glare Reduction for Both Public Safety and Energy Savings” [12]. Significantly that AMA view was broadened in 2012 when they said, “The (AMA) policy also supports the need for developing lighting technologies that minimize circadian disruption and encourages further research on the risks and benefits of occupational and environmental exposure to light at night” [13].

Outdoor lighting, because such lighting impacts the natural environment and so many people see it, use it, and experience it, has become complicated. It is now a social, technical, medical, and environmental problem that has to be carefully analyzed rather than a traditional exercise in illuminating engineering so that people can see. Light pollution issues contribute to outdoor lighting’s complexity, but light pollution also calls attention to important and growing outdoor lighting problems that have to be addressed and resolved.

LED sphere; Lighting arc; Lighting dome

Definition

A Light Stage is a device to illuminate an object or a subject under controlled illumination from a full sphere of surrounding directions. Light Stage illumination control, with control over light intensity, color, or direction, is usually performed in conjunction with photographing an object or subject's reflectance response to incident illumination. This process of recording a subject under controlled illumination has various applications in computer graphics and vision such as relighting, lighting reproduction, or reflectometry.

Light Stage and Reflectance Field

The Light Stage was first introduced by Debevec et al. [2] for acquiring the reflectance field of a

human face. The process involved spiraling a spotlight source tracing a spherical path around a subject using a rope and pulley system while recording the subject's face with a video camera. The whole process required around a minute to complete light movement covering a full sphere of incident directions. This enabled the camera to record the response of the subject's face under a dense set of discrete lighting directions, with the set of acquired photographs referred to as a 4D reflectance field (2D for incident illumination direction $\times$ 2D for each photograph recorded by the camera). Such a 4D reflectance field enables image-based relighting of the acquired subject using a simple dot product of the reflectance field data with a desired lighting (represented as a spherical environment map) (see Fig. 1).

Various versions of the Light Stage have subsequently been developed for efficient capture of subject reflectance with applications in film visual effects [1]. Light Stage 2 was developed as a semicircular arc of strobe lights that could be rotated rapidly around a subject in 8 seconds. The device could be employed to rapidly acquiring facial reflectance fields of subjects in various facial expressions to build an animatable character [6]. This process was further extended with Light Stage 5 to record an actor's dynamic facial reflectance field using time-multiplexed illumination and high-speed photography [19]. This required a change in the Light Stage design, with a set of 156 bright white LEDs mounted on a 2 m

(b) Lighting reproduction

diameter geodesic structure surrounding the subject. Finally, reflectance field acquisition was further extended for full human body using Light Stage 6, a large 8 m diameter dome (two thirds of a full sphere) with more than 6000 bright white LEDs [4]. Figure 2a shows an alternate design of an LED sphere where, instead of a standard icosahedral subdivision of a sphere, 168 LED lamps have been mounted along latitudes-longitudes [9].

Lighting Reproduction

Besides image-based relighting, Light Stages can also be employed for direct lighting reproduction applications where an actor is lit inside a Light Stage with a desired lighting environment. This enables compositing the actor's imagery or performance into a virtual background with matching illumination. Debevec et al. [3] first proposed this process with Light Stage 3, which consisted of a geodesic spherical structure (same as Light Stage 5) with 156 programmable RGB LEDs. The device could be programmed to reproduce the colors and intensities of an HDR lighting environment on an actor at video rates. An example of this can be seen in Fig. 2b. The method has been employed in several film visual effects pipelines for illuminating actors in a studio environment for realistic digital compositing, e.g., in the film *Gravity* to illuminate actors wearing space suits with light from the surrounding space and Earth as seen from orbit [14].

More recently, the method of RGB illumination has been extended for improved spectral

lighting reproduction using a wider set of color LEDs including red (R), green (G), blue (B), cyan (C), amber (A), and white (W) by LeGendre et al. [11]. They demonstrated more accurate color reproduction with such an extended RGBCAW lighting compared to standard RGB lighting using USC-ICTs multispectral Light Stage X apparatus. A similar multispectral lighting capability has recently been achieved using a combination of RGB, and an extended set of white (W+) LEDs spanning warm, neutral, and cold color temperatures respectively [8] (see Fig. 3).

Facial Capture

More recently, Light Stage systems have been employed for high-quality facial capture including acquisition of detailed facial geometry and reflectance maps for realistic facial renderings. Such 3D facial geometry and reflectance data are better suited for standard visual effects rendering pipelines than the image-based data acquired for relighting or lighting reproduction applications. Debevec et al. first explored estimating 3D shape (in the form of a surface normal map) and diffuse and specular reflectance from the dense reflectance field of a face [2]. This process was further refined by Weyrich et al. [20] who employed an LED sphere with 150 lighting directions to acquire dense reflectance information of a face from 16 viewpoints for detailed facial reflectance modeling. However, these initial works required dense capture of facial reflectance data to compute

Light Stage, Fig. 3 Multispectral lighting using RGBW+ LEDs [8] (a), and their corresponding spectral response on an Xrite color chart (b)

the reflectance and normal maps for rendering (Fig. 4).

Ma et al. [12] introduced a step change in facial reflectance acquisition process with a Light Stage. They employed the Light Stage 5 LED sphere to rapidly illuminate a subject with four spherical gradient illumination conditions (one full-on uniform illumination, and three principal linear gradients in the X, Y, and Z directions) to estimate high-quality facial reflectance and normal maps. They further proposed polarizing all the lights on the LED sphere in a specific pattern to allow high-quality separation of diffuse and specular reflectance and normal maps from a frontal viewpoint (in conjunction with mechanical flipping of a linear polarizer in front of the camera). Besides high-quality facial rendering with hybrid normal mapping, the high resolution surface details estimated from the specular normal map could then be employed for very high resolution facial geometry reconstruction (including fine-scale surface details, such as skin pore and fine wrinkles). The capture method was however restricted to a single frontal viewpoint due to the polarization pattern on the LED sphere. This restriction was lifted by Ghosh et al. [5], who proposed a multiview polarization solution for facial capture. Their solution

involves the LEDs on the Light Stage to be partitioned into two orthogonal polarization banks producing lines-of-latitude (horizontal) polarization and lines-of-longitude (vertical) linear polarization, respectively. This allows high-quality diffuse-specular separation from camera viewpoints (with a fixed vertical linear polarizer) placed all around the equator of the LED sphere, enabling high-quality multiview facial capture. While the method was originally demonstrated using interleaved banks of lat-long polarization with Light Stage 5, it was subsequently adapted for facial capture using Light Stage X with individually controllable polarization banks in each lighting unit.

Facial capture with polarized spherical gradient illumination has been employed extensively for film visual effects, starting with scanning in Light Stage 5 for AVATAR and subsequent multiview facial capture in Light Stage X for many more recent films. The technique and apparatus have been recently recognized by the Academy of Motion Picture Arts and Science with a Technical Achievement Award in 2019 [15].

Under the assumption of pure diffuse surface reflectance, binary spherical gradient illumination has instead been employed for estimating

Light Stage, Fig. 4 Multiview facial capture with polarized spherical gradient illumination [5]. (a, b) LED sphere latitude-longitude polarization pattern and multiview

capture setup. (c) Acquired data with diffuse-specular separation, and the resulting reconstructed facial geometry and facial rendering

photometric normals for full-body performance capture (using Light Stage 6) [18]. Kampouris et al. [9] have recently demonstrated how binary spherical gradient illumination can also be employed for high-quality diffuse-specular separation of reflectance and photometric normals using color-space analysis (see Fig. 5). An advantage of this method over polarized spherical gradient illumination is that it reduces data capture by half, and the acquisition is more light-efficient and completely view-independent. Spectral multiplexing of the binary gradients further reduces data capture to just two photographs for view-independent diffuse-specular separation of albedo and photometric normals. Kampouris et al. employed a versatile multispectral Light Stage built with off-the-shelf components [8] for this purpose.

Object Capture

Specific Light Stage designs have also been developed for acquiring objects, particularly those exhibiting high frequency reflectance functions such as sharp specularity, or transparent objects casting sharp caustics. Hawkins et al. [7] introduced a dual Light Stage design that replaced a traditional Light Stage that usually has a discrete set of lights with a continuous spherical diffuse dome enclosing an object. The dual Light Stage exploits the property of reciprocity of light transport to indirectly record a reflectance function at very high resolution. It does this by placing an actuated laser source at the position of a desired virtual camera which illuminates the object with individual beams of laser light through a small hole in the dome. The object then reflects or

Light Stage, Fig. 5 A face acquired with binary spherical gradients and their complements (a–f) [9], and estimated diffuse and specular albedo (g, h) and photometric normal

maps (i, j), which enable realistic relighting with hybrid normal rendering (k)

Light Stage, Fig. 6 Diffuse-specular separation of reflectance (a) and photometric normals (b) with structured environmental illumination using a reflective Light Stage [10]

scatters the beam onto the diffuse spherical dome from where the reflectance distribution is seen by a camera placed above that records the dome reflection using a fish-eye lens. Reciprocity is used afterward to convert the camera image into a continuous reflectance function while the corresponding laser beam location is converted into a virtual camera pixel. The method allows relighting of highly specular or transparent objects without any aliasing artifacts that would be visible when employing a traditional Light Stage.

Peers et al. [13] proposed a simpler design of a reflective Light Stage that employs a projector with a fish eye lens and a reflective hemispherical

dome to illuminate sharp specular objects with continuous illumination covering the front hemisphere. The setup could be employed for image-based relighting using reflectance field acquisition, as well as reflectance separation (into diffuse and specular components) using structured environmental illumination [10] (see Fig. 6).

Besides acquisition of highly specular objects for image-based relighting, a continuous illumination Light Stage [17] has also been designed for acquiring surface reflectance (with diffuse-specular separation) and shape (in the form of normal map and surface geometry) of such objects

Light Stage, Fig. 7 A continuous Light Stage for illuminating specular objects with spherical harmonic illumination [17]. (a) Physical setup. (b) Acquired reflectance and

normal maps of Oakely sunglasses. (c) 3D rendering of sunglasses with acquired data

for standard rendering pipelines. Tunwattanapong et al. proposed employing a rotating LED arc to cover a full sphere of surrounding directions with continuous spherical illumination. Furthermore, they employed high frequency spherical harmonic illumination to separate reflectance of specular objects into diffuse and specular components, as well as estimate surface normals and spatially varying specular roughness over the sample for realistic rendering. Combining the setup with multiview acquisition enabled them to also acquire 3D geometry of such objects for rendering from a novel viewpoint (Fig. 7).

Synonyms

Electromagnetic spectrum – Optical spectrum; Light – Light stimulus, Optical radiation, Electromagnetic radiation

Definitions

Light is so much a part of our everyday existence contributing to our quality of life, as well as a key enabler in photonics, solar power, and new lighting technologies, that the year 2015 was declared by the UNESCO as the International Year of Light and Lighting Technologies.

Light has many different meanings depending upon the application.

When it is used to broadly describe *optical radiation*, it is defined as electromagnetic radiation with wavelengths between approximately 10 nm and 1 mm, i.e., a term that is used to describe the ultraviolet, visible, and infrared regions of the electromagnetic spectrum.

When it is used to describe a *light stimulus*, the International Lighting Vocabulary [1] gives the following two definitions: (1) It is a characteristic of all sensations and perceptions that is specific to vision and (2) it is radiation that is considered from the point of view of its ability to excite the human visual system, i.e., it is limited to electromagnetic radiation with wavelengths in the visible spectral region between approximately 380 and 780 nm.

The term *light* is also sometimes used as a synonym for *electromagnetic radiation* (emr). However, emr encompasses not only the ultraviolet, visible, and infrared range but also the X-ray and gamma-ray ranges <10 nm and the microwave and radiowave ranges >1 mm. The use of the term *light* for this extended emr range of wavelengths should be avoided.

Electromagnetic radiation is the emission or transfer of energy in the form of electromagnetic waves and in the form of photons.

Photon is a quantum of electromagnetic radiation that is usually associated with radiation that is characterized by one wavelength or frequency (monochromatic radiation).

Electromagnetic wave is a transverse oscillation of inextricably linked electric and magnetic fields traveling through space; through empty space, it travels at the speed of light in vacuum; through other media, its speed is reduced by the value of the refractive index of the medium.

Electromagnetic spectrum is defined as the graphical representation of electromagnetic waves arranged according to their wavelength.

Overview

Early Views of Light

The nature of light has intrigued philosophers and scientists for thousands of years. Because light travels in straight lines (*rectilinear propagation*), it was long believed that it was made of particles (corpuscles) that emanated from the source. However, some properties of light, such as the fuzziness produced when light passes around obstacles or through openings (*diffraction*), needed a different model of light where it behaved like a type of wave or propagating disturbance. In the early 1700s, both the particle and wave models of light prevailed with Sir Isaac Newton being a staunch supporter of the particle theory and others, such as the Dutch physicist, Christiaan Huygens, being proponents of the wave theory [2]. But, in the early 1800s, when the English physician Thomas Young showed that light diffracted and interfered to produce fringes when it passed through a double slit, the wave model of light became the accepted theory. At the end of the nineteenth century, the particle theory of light was revived by Einstein, who used particle behavior and a new type of theory – quantum physics – to explain the photoelectric effect. It is now widely accepted that light exhibits all three of these behaviors: particle, wave, and quantum, which are used to explain all known properties of light [2].

The history of light has also included interesting debates on how it is propagated. Ancient astronomers thought that light traveled at infinite speed. The Greek philosopher Aristotle proposed that light propagated through a hypothetical substance, luminiferous ether or light-bearing ether, because it was believed that all types of waves required a medium for propagation such as sound waves in air and water waves in water. However, light is very different from other types of waves. In 1881, in one of the most famous experiments with light, Michelson and Morley tried to measure the rotational motion of the earth in this

luminiferous ether [2]. However, they found that the light did not travel at different speeds for different paths. This failed experiment indirectly showed that light does not need a medium and can travel in free space (vacuum) and at constant speed. Michelson also carried out experiments to measure the speed of light by improving on Galileo's echo technique by replacing men carrying lanterns with a series of mirrors and a telescope. By adjusting the rotation speed of the mirrors, he could observe the light in the telescope, and from the rotation of the mirror and the known distance traveled by the light, he was able to determine the speed of light to about six significant figs [2]. Presently, the speed of light is the most accurately known fundamental constant of nature.

Description of Electromagnetic Radiation and Light

Electromagnetic radiation (emr) can also be described as the emission or transfer of energy from vibrating charged particles that creates a disturbance in the form of oscillating electric and magnetic fields (Fig. 1). The British physicist James Clerk Maxwell [3] was the first to discover that these electric and magnetic waves always occurred together, i.e., were coupled, giving rise to the name, *electromagnetic waves*. It was also found that the lines of force of these electric and magnetic waves were always perpendicular to each other and perpendicular to the direction of wave propagation, i.e., *transverse*, never longitudinal. This *transverse* nature of light gives rise to various phenomena associated with *polarization*.

Polarized electromagnetic radiation is defined as radiation whose electromagnetic field, which is transversal, is oriented in defined directions [1, 4] where this polarization can be linear, elliptic, or circular. Light is totally linearly polarized (or *plane polarized*) if the electric field vectors are all oriented in the same plane, parallel to a fixed direction which is referred to as the *polarization direction*. Light is *unpolarized* when its electric field vectors vibrate randomly in all directions; this can also be considered to be equal amounts of plane-polarized radiation whose

Light, Electromagnetic Spectrum,

Fig. 1 Simplified picture of an electromagnetic wave. The oscillations are perpendicular to each other and to the direction of energy flow

vibration directions are perpendicular to each another. The *state of polarization* of the radiation (linear, circular, and elliptic) is described by the phase relationship between these two orthogonal components. If this phase difference is zero or 180° , the radiation is *linearly polarized*; if the phase difference is 90° or 270° and both components have the same amplitude, the radiation is *circularly polarized*; and if the phase difference is not 0° , 180° , 90° , or 270° and/or the amplitudes are different, the radiation is *elliptically polarized*.

Light is *partially polarized* if the electric vectors have a preferred direction. If the electric vector is polarized vertical to the plane of incidence, this is referred to as *s-polarized* (or TE), and if the electric vector is polarized parallel to the plane of incidence, this is referred to as *p-polarized* or (TM).

In addition to its state of polarization, these *electromagnetic waves* are characterized by several other measurable properties, such as the number of oscillations per second, the separation between successive peaks or troughs, and the size or amount of oscillations. These quantities are described by the frequency, ν ; wavelength, λ ; and amplitude or intensity, I , respectively. The *intensity* describes the amount of energy flowing in the electromagnetic wave and is proportional to the square of the *amplitude*. It is also necessary to specify the *direction* that the wave is traveling, which is indicated in Fig. 1 by using an arrow. It can be seen that these waves crest up and down in a sinusoidal fashion, which is described as the *wave front* moving up and down. When more than one wave is traveling, it is important to describe how they differ in phase. Two waves

are *in-phase*, if their crests coincide and their troughs coincide. Two waves are *out-of-phase*, if the crest of one wave coincides with the trough of the second wave and vice versa. A *plane wave* is a wave whose surfaces of constant phase are infinite parallel lines transverse to the direction of motion. If all of the waves vibrate in-phase, the emr is referred to as *coherent*. The laser is an example of a coherent light source. If there is no fixed phase pattern between the waves emitted by a light source, the emr is referred to as *incoherent*. Most ordinary light sources, such as an incandescent lamp, are examples of incoherent light sources.

Properties of Electromagnetic Waves

As mentioned above, generally a wave, such as a water wave, is a propagating disturbance of some equilibrium state in a continuous medium. However, no medium is required for propagation of electromagnetic waves. This property of electromagnetic waves makes them unique from other types of waves that can be considered mechanical in nature and was first demonstrated by Einstein in 1905. He also proposed the idea that light could behave both as a wave and as a particle in order to explain the spectral distribution of the radiation emitted from a hot (incandescing) object. This type of electromagnetic radiation is referred to as *blackbody radiation*.

Electromagnetic waves of all wavelengths travel exactly at the same speed in vacuum. This fundamental constant of nature is known as the *speed of light in vacuum*, denoted by the symbol,

c. It has a value of 299,792,458-meter per second. The frequency, ν , is related to wavelength, λ , by $\nu = c\lambda^{-1}$. Waves are also sometimes described by their *wave number*, σ , which is the inverse of wavelength, defined by $\sigma = \lambda^{-1}$.

When an electromagnetic wave travels through other media such as air, glass, or water, its frequency remains constant, but its wavelength and speed are both reduced by a factor, n , the *refractive index* of the material. For commonly used optical glasses, the value of n ranges from 1.52 to 1.72 and is a function of frequency. For standard air, n has a value of 1.00028 [5] and can be ignored for most practical applications.

The behavior of electromagnetic waves at the boundary from one medium to another giving rise to reflection, transmission, and refraction phenomena is described by a set of wave equations known as *Maxwell's equations* [6].

These four equations have become the fundamental laws in electromagnetics connecting the principles of electricity and magnetism. Solving these equations reveals the wave equation and the form of the electromagnetic waves. The Maxwell's equations are not given here because this is outside the scope of this entry; the interested reader can find a good description in the following references [2, 6].

The smallest unit or quantity of electromagnetic radiation is called a *photon*. The energy of a photon is given by $E = h\nu$ where h is Planck's constant ($6.62607015 \times 10^{-34}$ Js). Light can then be described as a stream of individual photons, each with a definite energy and that can interfere with each other like waves and diffract around corners [3]. The motion of these photons is controlled by these same set of Maxwell wave equations [2, 3].

The *electromagnetic spectrum* spans the total range of wavelengths of electromagnetic radiation from the shortest to the longest wavelength that can be generated physically. This range of wavelengths spans practically from zero to near infinity and can be broadly divided into regions as shown in Table 1 [7], which includes radio waves, infrared, visible, ultraviolet, X-rays, and gamma rays. This division is not exact since there is a gradual transition from one region to the next, which is

Light, Electromagnetic Spectrum, Table 1 Regions of the electromagnetic spectrum

Wavelength range (nm)	Frequency range (s ⁻¹)	Description
<0.1 nm	10 ²⁰ –10 ²³	Gamma rays
0.1–10 nm	10 ¹⁷ –10 ²⁰	X-rays
10–400 nm	10 ¹⁵ –10 ¹⁷	Ultraviolet
400–700 nm	10 ¹⁴ –10 ¹⁵	Visible
700 nm to 1 mm	10 ¹¹ –10 ¹⁴	Infrared
1 mm to 1 cm	10 ¹⁰ –10 ¹¹	Microwaves
1 cm to 100 km	10 ³ –10 ¹⁰	Radio waves
100–1000 km	10 ² –10 ³	Audio frequency

shown schematically in Fig. 2 where the visible and ultraviolet regions are highlighted. This classification of light into regions is also shown as a function of frequency. It is important to note that the only difference between electromagnetic radiations in all these regions is its wavelength (and frequency). It has different descriptions because of the relationship between its frequencies and those that are excited in the various materials that the electromagnetic radiation can interact with. For example, the visual receptors in the human eye are only sensitive to electromagnetic radiation in a very narrow frequency range from 10¹⁴ to 10¹⁵ s⁻¹ (or 400–700 nm), whereas X-rays are used to excite features in the body that are of the size of an atom (0.1 nm). These different applications of emr are described in more detail below.

Interaction of Light with Matter

When light interacts with matter, different phenomena can occur depending upon the relationship of the wavelength (frequency) of the light with the physical size (resonant frequencies) of the interfering matter. This matter consists of atoms, ions, and molecules. As mentioned above, only light in the visible portion of the spectrum with frequencies from 10¹⁴ to 10¹⁵ s⁻¹ can stimulate the visual receptors in the human eye. Light can also exhibit wave or particle properties depending upon this relationship between

L

Light, Electromagnetic Spectrum, Fig. 2 The regions of the electromagnetic spectrum, highlighting the optical spectrum which includes the visible and ultraviolet regions

size (or frequency). For light waves that are closely spaced in relation to the spacing of the interfering matter, for example, a wave front passing through a slit or an opaque edge, secondary wave fronts are generated. These will interfere with the primary wave front, as well as with each other, and produce *diffraction* patterns. Since these secondary wave fronts were produced from the same primary wave, their phase will change in step. Thus, even for a normally incoherent light source, wave-like behavior such as *diffraction* and *interference* can be seen under certain conditions [8].

Many colorful effects are produced by this combination of light *diffraction* and *interference*. In nature, this can be seen, for example, in the beautiful array of colors displayed by mother of pearl (*opalescence*) or by thin film *iridescence*. For light waves that are very small in relation to the interfering particles, such as the interaction of visible light with dust particles or gas molecules in the atmosphere, *Rayleigh scattering* occurs which produces the blue color of the sky.

However, when light interacts with objects that are large in relationship to their wavelength, such as a brick wall or pane of glass, the light behaves more like a ray (particle) and the laws of geometrical optics can be applied.

Depending upon the transparency or translucency of the material and its surface quality, the light will be reflected, refracted, transmitted, absorbed, or scattered. The type of light interaction that dominates depends upon the precise nature of the matter, e.g., for a smooth opaque colorless solid, specular (mirror-like reflection) will dominate, whereas for an opaque colored material, diffuse reflection or scattering will dominate. The selective modification of the energy distribution of the incident light by the diffusely reflecting material gives rise to different colors.

Light Intensity Distribution and Color

The different wavelengths in the visible spectrum can also directly stimulate different colors in the human visual system. This dependence of color on wavelength is shown in Table 2.

Radiation of a single wavelength is called *monochromatic*. Except for lasers and certain specialized lamps, most sources of optical radiation emit energy over a broad wavelength region. The curve describing the power at each wavelength is called the *spectral power distribution* (SPD). A color stimulus generally has an SPD that varies with wavelength across the visible spectrum

producing a color or sensation that is a shade or mixture of the colors listed in Table 2. Stimuli containing all the visible wavelengths in roughly equal proportions appear white.

This is demonstrated by passing white light through a glass prism, which spreads the light out into a spectrum of colors (see Fig. 3).

However, white light can also be produced by superimposing discrete monochromatic lights. For example, white light can be produced by superimposing red, blue, and green lights in certain proportions. This was first demonstrated by Thomas Young [3] who used this experimental finding to theorize that the human eye contained three different types of color receptors, which is known as the trichromatic theory of human color vision.

Because of this trichromacy, white light can be produced by many different SPDs. The variation in these SPDs is illustrated in Fig. 4, which shows the SPD of a typical tungsten lamp, a fluorescent lamp, a white LED source produced by a blue LED and yellow phosphor, and noon daylight. The most prevalent source of light in our natural environment – the sun – has an SPD that can

change dramatically during the course of the day, from a bluish cast at noon to a reddish-orange cast at sunset. These variations in SPD of the light source are very important for visual evaluations of colored goods. For this reason, the SPDs of different phases of daylight have been standardized by the International Commission on Illumination (CIE) as a series of D illuminants. Shown in Fig. 4 is the SPD of CIE standard illuminant D65, which is average daylight with an approximate correlated color temperature of 6500 K.

Applications of Electromagnetic Radiation

The applications of electromagnetic radiation (emr) cover almost all aspects of our daily lives. The importance of visible light for human vision has already been discussed. Light emanating from the sun spans the solar wavelength region from about 250 nm in the UV to 2500 nm in the near-infrared region. This solar radiation is extremely important to the energy balance of the earth and for various building design applications, such as the design of glazing materials. It is also exploited in light-based technologies, such as photovoltaics.

Light in the infrared region of the spectrum is felt as heat and is used in the design of radiant heating, solar panels, and collectors. The frequencies in the infrared region are close to the resonant vibrational frequencies in molecules and can be used for molecular identification by spectroscopic means. Similarly, the frequencies in the

Light, Electromagnetic Spectrum, Table 2 Dependence of color on wavelength

Wavelength range (nm)	Color
400–430 nm	Violet
430–480 nm	Blue
480–560 nm	Green
560–590 nm	Yellow
590–620 nm	Orange
620–700 nm	Red

parentheses: top left: tungsten lamp (CIE A); bottom left: noon daylight (CIE D65); top right: fluorescent lamp (FL12); and bottom right: blue LED + yellow phosphor

microwave region are close to the resonant rotational frequencies in molecules, in particular the water molecule. Since most foods contain a significant amount of water, the microwave radiation heats the food by the increased rotational motion of the interspersed water molecules. These microwaves pass through glass, ceramic, and plastic but reflect from metal which can also be used to advantage in the selection of the food container and walls of the microwave, respectively.

Light in the ultraviolet (UV) region has many important uses. In the early nineteenth century, it was called “chemical rays” because it was found that UV radiation could cause chemical changes. This was used to advantage to harden special glues in inks, coatings, and adhesives more quickly, in a process called UV curing through polymerization. The skin of our bodies needs exposure to UV with wavelengths in the region

280–315 nm (UVB) in order to stimulate the production of vitamin D. However, too much exposure to UVB can cause skin cancers, so it is important to find the optimum exposure level. UV light with wavelengths in the region 200–280 nm (UVC) is called “germicidal UV” because it has sufficient energy to inactivate bacteria and viruses by disabling their DNA strands. For this reason, it is also used for sterilization of surfaces such as medical equipment. This type of UVC radiation is often produced by a low-pressure mercury vapor lamp (see Fig. 2). UV radiation is also needed to excite a class of molecules referred to as fluorescent-whitening agents (FWAs) or optical brighteners in manufactured white goods, such as paper, fabrics, detergents, soaps, and cosmetics, which emit in the blue portion of the visible spectrum and produce an enhanced whiteness effect. UV radiation is also of the appropriate frequencies

to absorb ozone molecules in the atmosphere so very little UV radiation reaches the earth's surface.

X-rays have a higher frequency than UV radiation and can pass through the skin and soft tissue, but they do not easily pass through the bone or metal. This type of emr is used to produce photographs of bones in medical diagnostics to check for damage such as fractures. The frequencies of gamma radiation, on the other hand, are more penetrating and can destroy chemical bonds by interacting with the electrons of the constituent atoms or disrupt DNA bonds, resulting in prevention of cellular division. This can be used to advantage to kill microorganisms throughout the material. Gamma sterilization is used, for example, in sterilization of water and food products.

Other important applications of emr are radio, television, and electric current.

Light-Emitting Diode, LED

Wout van Bommel
van Bommel Lighting Consultant,
Nuenen, The Netherlands

Synonyms

[Optoelectronic light source](#); [Solid-state light source](#)

Definition

A light source that produces light as a result of recombination of positively charged holes and negatively charged electrons at the junction of inorganic, solid-state, p- and n-type semiconductor material.

Solid-State LED Light Sources

LEDs are solid-state radiators where the light is created inside solid-state material [1–3]. Common semiconductor diode chips, used today in so many electrical circuits, all use much the same technology. The light-radiating diode versions are called light-emitting diodes or LEDs. The name LED is commonly used for light-emitting diodes made of inorganic semiconductor material; they are point light sources. Light-emitting diodes made of organic semiconductor material are referred to as OLEDs; they are planar light sources. A separate chapter deals with OLEDs.

Until the mid-1990s of the last century, LEDs had a low lumen output and low efficiency, making them only suitable as small indicator lamps (e.g., in electrical appliances). Today, the efficacy of LEDs is comparable to that of gas discharge lamps. The lumen output of a single LED can be more than 1000 lm. To distinguish these LEDs from the indicator type of LEDs, they are referred to as high-brightness or high-power LEDs (Fig. 1). Further improvements in high-brightness LEDs are expected, ultimately leading to

Light-Emitting Diode, LED,

Fig. 1 Indicator lamp LEDs (*left*) and a high-power LED (*right*)

efficacies of probably slightly more than 200 lm/W (for white-light LEDs). This is approximately twice the efficacy of today's most efficient white-light gas discharge lamps. With its light-emitting surface of some 0.5–5 mm², an individual LED chip represents the smallest artificial light source. LEDs have a long lifetime and are, given the solid-state material, extremely sturdy. They are available in white and in colored-light versions. The colored versions are extensively used in traffic signs. Colored versions were also the first ones to be used on a large scale for lighting: specifically, the exterior floodlighting of buildings and monuments. Both the efficacy and the color quality of white LEDs have been improved so much that they are now used in many different lighting applications, including road lighting, indoor accent lighting, domestic lighting, and automobile lighting. Examples of the use of LEDs for office lighting and outdoor sports lighting can also be found. Given the potential for a further increase in their efficacy, the number of LED applications is bound to increase. Their small size and their availability in many different colors and the easiness of lighting control, both in terms of dimming and color changing, are properties that permit of entirely new applications.

Working Principle

Principle of Solid-State Radiation

Like any diode, an LED consists of layers of p-type and n-type of semiconductor material. The n-type of material has an excess of negatively

charged electrons, whereas the p-type material has a deficiency of electrons, viz., positively charged holes. Applying a voltage across the p-n semiconductor layer pushes the n- and p-type atoms toward the junction of the two materials (Fig. 2). Here the n-type of atoms “donate” their excess electrons to a p-type of atom that is deficient in electrons. This process is called recombination. In doing so, the electrons move from a high level of energy to a lower one, the energy difference being emitted as light. The wavelength of the light is dependent on the energy-level difference between the p and n materials, which in turn depends on the semiconductor material used: different semiconductor materials emit different wavelengths, and thus different colors, of light. The process is very much like the process of excited electrons in a gas discharge falling back to their original orbit with a lower energy level while emitting light. In this sense, it is surprising that the expression “solid-state discharge” and “solid-state discharge lamp” is hardly ever used. Not all recombinations result in light emission. Some recombinations are non-radiative and just heat up the solid material. This limits the efficiency of light creation. A further limitation of the efficiency is caused by absorption of light in the solid material of the chip itself. Improvements in radiative-recombination efficiency and light-extraction efficiency have been the most important reasons for the dramatic improvements in efficacy of LEDs during the past decade. Further improvements will be sure to further significantly increase the efficacy of LEDs over the coming decade.

Light-Emitting Diode, LED,

Fig. 2 Principle of operation of solid-state radiators

Light-Emitting Diode, LED, Fig. 3 White light by combining red, green, and blue LED light [4]

Like gas discharge lamps, solid-state lamps cannot function when they are operated direct from the mains supply voltage. Solid-state light sources are low-voltage rectifiers that allow current to pass in one direction only. This means that the AC mains supply has to be transformed to low voltage and then rectified into a DC supply. Small fluctuations in supply voltage cause large variations in current that can damage the light source. High-power LEDs need an electronic driver to obtain a constant current characteristic.

Principle of White LEDs

The spectrum of a single LED is always narrow. Consequently, its light is colored. White LED light can nevertheless be obtained by combining three (or more) different colored LED chips. A common method is to combine red, green, and blue LED chips into a single module to produce white light (RGB LED, Fig. 3). Sometimes the three chips are mounted in the same LED package (Fig. 4). The color rendering of an

Light-Emitting Diode, LED, Fig. 4 RGB chips mounted in the same LED package

“RGB white-light” system is not good, since large areas of the full-color spectrum are not included in its light. Sometimes an amber color chip is added to the RGB combination to improve the color quality of the light (RGBA LED). Research is going on to produce single, multilayer LED chips, each layer producing a specific color of light. A single LED producing red, green, and blue light would, therefore, result in white light.

Good-quality white light, which is especially important when it comes to providing good color rendering, is obtained by using a blue LED chip in combination with a fluorescent material that converts much of the blue light into light of different wavelengths spread over almost the whole visible spectrum. In LED technology it is customary to call such fluorescent materials, phosphors: hence white LEDs based on this principle are called “white-phosphor LEDs.” By mixing different phosphors in different proportions, white LEDs producing different tints of white light with different color-rendering capabilities can be made.

Materials and Construction

The LED chip is embedded in a larger structure for mechanical protection, for the electrical

Light-Emitting Diode, LED, Fig. 5 The main components of a high-brightness LED [4]

connections, for thermal management, and for efficient light out-coupling. The main parts of an LED are (Fig. 5):

- Semiconductor LED chip
- Reflector cup
- Supporting body
- Electrodes and bond wires
- Heat sink
- Primary optics
- Phosphors (for white LEDs)

Semiconductor Chip Material

The p-n semiconductor sandwich forms the heart of the LED and is called the LED chip or die. The semiconductor material used determines the wavelength and, thus, the color of the light emitted. For LEDs, compound semiconductor material is used, which is composed of different crystalline solids. These are doped with very small quantities of other elements (impurities) to give their typical n and p properties. For the colors blue, green, and cyan, the elements indium, gallium, and nitride (InGaN) are used in different compositions (Fig. 6, left). The elements aluminum, indium,

gallium, and phosphide (AlInGaP) are used to produce the colors amber, orange, and red (Fig. 6, right). It was the Japanese Nakamura who, in 1993, succeeded for the first time in producing a blue LED suitable for mass production. This was the “missing link” that enabled the production of white-phosphor LEDs and the production of white LED light on the basis of mixing the light of red, green, and blue LEDs. As can be seen from Fig. 6, today a very small area of the spectrum, in greenish-yellow, is still missing.

Shape of the Chip

Unfortunately, the LED chip is a “photon or light trap”: that is to say, much of the light emitted within the chip is internally reflected by its surfaces (borders between the material and air) and, ultimately, after multi-reflections, absorbed in the material (heating up the material). Only light that hits the outer surface more or less perpendicularly (approximately 20°) can leave the material. By giving the chip a specific shape and by keeping it thin, the so-called light-extraction efficiency can be improved. Figure 7 gives an example of such a specially shaped chip.

Light-Emitting Diode, LED, Fig. 7 An example of a specially shaped LED chip that improves light-extraction efficiency. On top of the chip, the anode with its bond wire can be seen [4]

Reflector Cup

In many cases, the chip is placed in a reflector cup which, because of its shape, helps to direct the light in an upward direction. Highly reflective material is used, for example, metal or ceramic material.

Primary Optics

The silicon lens on top of the LED chip serves as protection for the chip. More importantly, it helps in increasing the light extraction from the chip and as such is essential for a high lumen efficacy of the LED. This is because by introducing a lens medium between the chip and the air with a refractive index value between that of air and that of the chip material, the angle over which light can escape from the chip increases.

Electrodes and Bond Wires

In order to be able to apply power to the chip, the p and n parts of the chip have metal contacts called electrodes. Bond wires connect the electrodes with the electrical connections. They are usually gold wires. Since the electrodes intercept light leaving the chip, the dimensioning of the electrodes and bond wires, especially on the side of the main light-escape route, is one of the factors that determines the light efficiency of the LED.

Heat Sink

LEDs do not radiate infrared radiation and consequently give a cool beam of light. However, this

does not mean that they do not generate heat. Non-radiative recombinations of electrons and holes in the p-n sandwich and light trapped in the chip do heat up the chip. The larger the power of the chip and the lower its luminous efficacy, the higher is this heating effect. The higher the temperature of the p-n junction in the chip, the lower the light output of the chip. A too-high chip temperature also severely shortens LED life, and it also slightly shifts the emitted wavelength and thus the color of the LED. Effective thermal management is therefore critical for the proper functioning of LEDs. All high-power high-brightness LEDs, therefore, have a heat sink of high-thermal-conductivity material (like aluminum or copper) on their rear side to conduct the heat away from the chip toward the outside world through the luminaire housing. LED luminaires must, therefore, incorporate in their design thermal conduction and convection features (such as cooling fins, Fig. 8) to dissipate the heat to the immediate surroundings. For retrofit LED lamps (LED bulbs), the size of the heat sink is limited by the size of the bulb. The heat sink, therefore, has a limited capacity, thus limiting the power of the retrofit LED bulbs.

Phosphors

As mentioned above, the most important method for producing white light with LEDs is by applying a phosphor coating to a blue-light LED that converts part of the blue light into longer-wavelength, green, yellow, and red light. Different compositions of different phosphors are used to produce white light of different color tints. Since the basis of the process is the blue light of the chip, the final efficacy will become higher as more blue is kept in the light. However, this implies a high color temperature (cool-white light) and relatively poor color rendering. If with a different phosphor composition, more blue light is converted, the color quality will improve at the expense of a somewhat lower efficacy.

Phosphors Applied Direct to the Chip The phosphor is often applied on or very near to the blue LED chip (Fig. 9). The thickness of the layer has to be very uniform as a variation in thickness

Light-Emitting Diode, LED,

Fig. 8 Examples of luminaires with cooling fins

Light-Emitting Diode, LED,

Fig. 9 Principle of creating white light with a blue-light chip covered with phosphor

Light-Emitting Diode, LED,

Fig. 10 Principle of a remote-phosphor LED module creating white light [4]

of the phosphor layer causes a variation of the color temperature in the light beam.

Remote Phosphor In the case of multi-LED units, the phosphor is sometimes applied at a greater distance from the LEDs. Such modules are called remote-phosphor LED modules (Fig. 10). Here, a number of blue LEDs are placed inside a mixing chamber of high and diffuse reflective material. The phosphor layer, positioned remotely from the LEDs on the bottom of the chamber, converts the blue light of the chips into white light. In this way, thanks to the mixing process, small differences in light output and/or color of individual chips are not visible. The risk

for disturbing glare is also reduced because the light intensity from the large-sized phosphor layer is much lower than the intensities of small, individual LEDs. In regular phosphor LEDs, the hot LED heats up the phosphor that is applied on the LED itself, reducing its conversion efficiency. Heating of remote positioned phosphor is much less, and thus the conversion efficiency of remote-phosphor systems is higher. In regular phosphor LEDs, a relatively large amount of light from the LED is reflected back from the phosphor toward the LED and absorbed there. In the remote-phosphor situation, most of the light reflected back from the phosphor layer takes part in the mixing process without reaching the LEDs, thus

Light-Emitting Diode, LED, Fig. 11 LED cluster module with multiple LEDs mounted on a printed circuit board

further increasing the final efficiency of the system. The phosphors used for the blue-light conversion appear yellow when they are not activated, that is to say, when the LED is not switched on (see Fig. 10 right). This sometimes makes people think, erroneously, that the blue light is filtered through a yellow filter. It is really wavelength conversion and not light filtering that takes place.

LED Cluster Modules

The luminous flux of one individual LED is quite low compared to that of most conventional light sources. Multiple LEDs are therefore often mounted on a printed circuit board (PCB) to obtain an LED module emitting a high luminous flux (Fig. 11). The PCB establishes the electrical connections between all components and the external electrical driver. The PCB must also conduct the heat from the heat sinks of the LEDs to the outside world.

Properties

Temperature of the Chip Junction

It has already been mentioned that with rising temperature of the p-n chip junction, the

performance of LEDs decreases: particularly the light output and lifetime. The performance data are usually specified for a junction temperature (T_j) of 25 °C. However, under normal operating conditions, a junction temperature of 60–90 °C is easily obtained. Depending on the LED type, the lumen output falls to 60–90% when the junction temperature increases from 25 °C to 80 °C. Amber and red LEDs are the most sensitive to changes in junction temperature and blue LEDs the least.

Binning

The mass production of LEDs results in LEDs of the same type varying in color, light output, and voltage. In order to ensure that LEDs nevertheless conform to specification, LED manufacturers use a process called binning in their production process. At the end of the manufacturing process, LED properties are measured, and LEDs are subsequently sorted into subclasses or “bins” of defined properties. As far as the color quality is concerned, the tolerances in these definitions (based on MacAdam ellipses) are such that visible differences in color between LEDs from the same bin are minimized. As the definition of a bin does not change with time, the same quality is also assured from production run to production run.

With the advancement of knowledge concerning LED materials and the mass production process, it may be expected that binning will ultimately no longer be required (“binning-free LEDs”).

Energy Balance

The energy balance of an LED is much easier to specify than that of conventional light sources. This is because no energy is radiated in the UV and infrared region of the spectrum, which means that the energy balance comprises only visible radiant energy and heat energy. Today, white LEDs transform 20–30% of the input power into visible light and the remaining part into heat. The light percentage comes close to that of fluorescent lamps and will soon supersede it.

System Luminous Efficacy

Sometimes, luminous efficacies are specified for the bare chip. It is evident that the ancillary

devices described in the previous sections, which are essential for the proper functioning of LEDs, absorb light. The only sensible thing to do, therefore, is to specify luminous efficacy (and light output as well) for the total LED package. As with most conventional lamps, the luminous efficacy of LEDs is dependent on the power of the LED and on the color quality of the light it produces. Higher-power LEDs have higher efficacies, while those with better color rendering have lower efficacies. Today cool-white LEDs are commercially available in efficacies up to some 150 lm/W and warm-white LEDs with color-rendering indices larger than 80 in efficacies of around 130 lm/W (all lm/W values include driver losses). Retrofit LED bulbs with warm-white light (around 2700 K) and color-rendering index better than 80 are available in efficacies up to 80 lm/W. Here, too, cooler-white versions are slightly more efficient.

As discussed at the beginning of this chapter, in coming years, it may be expected to see further important improvements in luminous efficacies for white LEDs – even up to slightly more than 200 lm/W.

Lumen-Package Range

Today, single LEDs exist in lumen packages varying from a few lumens (indicator lamps) to more than 1000 lm. In the latter case, severe screening is called for to restrict glare, because so much light comes from such a very small light-emitting

surface. By mounting multi-LEDs on a printed circuit board, LED modules can be achieved with much larger lumen packages.

Color Characteristics

Principally, LEDs have a quasi-monochromatic, narrow-band spectrum. Figure 12 shows the spectra of blue, green, and red LEDs. The half-maximum width of the spectrum bands is smaller than ca. 50 nm. It has already been shown what colors can be produced by using different semiconductor materials (see Fig. 6). With some LED modules, different colored LEDs can be controlled (dimmed) individually. With such LED modules (e.g., making use of RGB LEDs), the color of the light can be dynamically changed from white to all colors of the spectrum.

White-phosphor LEDs can have a near-continuous spectrum (Figs. 13 and 14). By applying different phosphors, white light within the color temperature range of 2700–10,000 K can be produced. Often, the higher-color-temperature versions have only moderate color rendering (R_a between 50 and 75). In the lower-color-temperature versions, LEDs are available with good (R_a larger than 80) to excellent color rendering (R_a larger than 90 or even 95).

Beam Control

For lighting designers, one of the most exciting properties of an LED is its small light-emitting surface. This allows the creation of very

L

accurately defined beams. As an illustration of this, Fig. 15 shows a near-parallel light beam made with an LED-line luminaire that is impossible to create with conventional light sources. The other side of the coin is that small light-emitting surfaces often need professional screening in order to limit excessive glare. Multi-LED luminaires also have multi-light beams that may cause multiple shadows because a lighted object is illuminated from many slightly different directions. With RGB color mixing, this may lead to disturbing, multicolored shadows.

Lifetime

In the case of high-performance LEDs, it takes a very long time before they actually fail – usually considerably more than 50,000 h. Before that

time, however, their lumen depreciation is so significant that the LED is no longer giving sufficient light for most applications. Therefore, for LED lifetime specifications, the length of time that it takes to reach a certain percentage of its initial light value is used. Based on a depreciation value of 70%, lifetime values of between 35,000 and 50,000 h are common for high-performance LEDs. LED bulbs, with their limited space for handling heat, have a lifetime of some 25,000–35,000 h (25–35 times longer than an incandescent lamp).

Lumen Depreciation

The electric current passing through the chip's junction, and the heat generated in it, degrades the chip material and is so responsible for light

depreciation. Decoloration of the housing and yellowing of the primary lens may be further reasons for the lumen depreciation. In white-phosphor LEDs, chemical degradation of the

phosphor material also causes lumen depreciation. As mentioned above in the section on LED lifetime, for high-performance LEDs, 30% lumen depreciation is reached at around 35,000–50,000 h.

Light-Emitting Diode, LED, Fig. 15 A near-parallel light beam with an LED-line luminaire [4]

Run-Up and Reignition

LEDs give their full light output immediately after switch on and after reignition.

Dimming

LEDs can be dimmed by simple pulse-width modulation down to 5% of full light. Not all retrofit LED lamps can be dimmed on regular, commercially available dimmers. Special retrofit LED lamps that are designed to be dimmed on such dimmers are so specified on their packaging.

Ambient-Temperature Sensitivity

As has already been mentioned several times, limitation of the junction temperature of the LED chip is essential for the proper functioning of LEDs in terms of lumen output, lumen efficacy, lamp life, and even color properties. In high-temperature environments, the products perform worse, while at low temperature they perform

better. The actual influence of the junction temperature is different for the different types of LEDs. In extreme temperature environments, therefore, relevant information for a particular product has to be obtained from the manufacturer.

Mains Voltage Variations

LED drivers are designed to drive LEDs on constant current. In this way the influence of mains voltage variations is not an issue.

UV and IR Component

LEDs radiate only visible radiation. There is no ultraviolet or infrared radiation.

Product Range

LED products are available as:

- Single LEDs (Fig. 16).
- Multiple LEDs on flat or three-dimensional PCB boards (Fig. 17).
- LED modules (or LED engines) with secondary optics and with or without built-in driver that can be used in the same way as lamps. Interfaces are standardized for interchangeability (Fig. 18).
- Multiple LEDs on strings (Fig. 19).
- Retrofit LED lamps with built-in driver and conventional design (Fig. 20); new types of designs are introduced for retrofit LED lamps as well (Fig. 21).

Light-Emitting Diode, OLED

Wout van Bommel
van Bommel Lighting Consultant, Nuenen, The Netherlands

Synonyms

[Optoelectronic light source](#); [Solid-state light source](#)

Definition

A light source that produces light as a result of recombination of positively charged holes and negatively charged electrons at the junction of organic, solid-state, p- and n-type planar semiconductor materials.

Solid-State Light Sources

LEDs are solid-state radiators where the light is created inside solid-state material [2–4]. The light-radiating diode versions are called light-emitting diodes or LEDs. Light-emitting diodes made of organic semiconductor material are referred to as OLEDs; they are planar light sources (Fig. 1). Organic semiconductor material is a chemical compound whose molecules contain carbon and hydrogen (C-H bonds). A property of carbon is that it can link with other carbon atoms to form long chains, a process called polymerization. The chains are called polymers. Artificially (synthetically) produced polymers are called plastics. Semiconductor polymers can be produced as thin films with a thickness of 10 to 100 nm. They combine the electric properties of semiconductors with the mechanical and chemical properties of plastics. These semiconductor films can be used to make relatively large-sized planar light sources of relatively low luminance with an inherently diffuse light distribution.

Serious development of commercial OLEDs only started around the year 2000. Initially,

expectations were that a relatively fast increase in luminous efficacy to more than 100 lm/W and in dimensions of much more than 1 x 1 m would be possible. Expectations today are that developments will be distinctly slower (Fig. 2). OLEDs can be produced to give most colors of the spectrum and white. The technology permits producing OLED windows that are transparent when not switched on (Fig. 3). Currently, an important application for OLEDs is displays for mobile phones and other display screens including television screens. Today, the most interesting lighting application for OLEDs is decorative lighting. For general lighting purposes, the efficacies are still too low.

Working Principle

The process that is responsible for the emission of light in OLEDs is very similar to that of inorganic LEDs: positively charged holes and negatively charged electrons are pushed through semiconductor layers toward each other and recombine (see the entry ► “[Light-Emitting Diode, LED](#)”). Part of these recombinations results in the emission of light. The color of the light is dependent on the composition of the semiconductor material. White light can be obtained by combining layers that emit different wavelengths (including red, green, and blue) or by bringing phosphorescent materials or quantum dots in the emissive layers. The number of layers varies and is dependent on the desired spectrum and the technology used.

Light-Emitting Diode, OLED,

Fig. 3 OLED window [1]

Materials and Construction

The semiconductor organic layers are placed between electrodes, the one on the light-escape side being transparent (Fig. 4). The layers are supported by a glass substrate and, for protection of the organic materials against oxygen and water, are sealed in glass. Development is going on to substitute the glass seal by thin-film encapsulation. This development not only reduces the thickness and weight of OLEDs but also opens up the possibility of bendable OLEDs. The first laboratory examples have already been produced.

Properties

System Luminous Efficacy and Brightness

Commercially available white OLEDs now have efficacies around 55 lm/W. Ultimately, white-light, large-sized OLEDs with efficacies up to 150 lm/W would seem to be possible (see Fig. 2). Products with luminance values of up to 3000 cd/m² have been shown. Compare this with a luminance value of some 6000–10,000 cd/m² of fluorescent tubes.

Light-Emitting Diode, OLED,

Fig. 4 Composition of an OLED [1]

Dimensions

The OLED panel can be as thin as 1 mm. Planar dimensions of commercially available OLED panels for lighting purposes go up to some 1×1 m.

Lifetime

Based on a lumen maintenance value of 70% (L70), lifetime values of high-quality OLEDs have reached 30,000 hrs, while values of 50,000 hrs have been reported.

Color Properties

The quality of white-light OLEDs depends on the combination of the semiconductor and phosphorescent materials used. Spectra similar to those of inorganic LEDs are obtained (see Fig. 11.32). As with LEDs the CCT range of OLEDs goes from 2500 K to 10,000 K. Color rendering varies from poor to excellent.

Light Distribution

The light distribution of an OLED panel is inherently diffuse (Lambertian distribution) and its luminance uniform. Light beam shaping techniques, possibly integrated with light extraction improving technologies, making use of, for example, microlenses or layers of optical films applied on top of the panel, have been described.

Run-Up and Reignition

OLEDs, like LEDs, give their full light output immediately after switch-on and after reignition.

Dimming

OLEDs can be dimmed by pulse-width modulation (PWM dimming) or by reducing the drive

current (analogue dimming). The advantages and disadvantages of both methods are described in the next section.

Ambient-Temperature Sensitivity

As in the case of LEDs, also OLEDs perform better at low temperatures (efficacy and lifetime) than at high temperatures. The modeling of the stacked structure and the use of temperature-tolerant material are critical factors in obtaining acceptable ambient-temperature sensitivities. Relevant information on the actual temperature sensitivity of a specific OLED type has to be obtained from the manufacturer.

Synonyms

[Lighting control systems](#); [Lighting management](#)

Definition

Lighting controls are intelligent network-based lighting solutions. They incorporate the communication between various system inputs and outputs related to lighting control. Input can be given manually by humans and/or by sensor signals or parameter settings. Part of the control systems are unusually one or more local or central computing devices.

Basics

Lighting control is understood to mean the manual or automatic tuning of a lighting situation inside a building, fixed to a building, or in an outdoor area. In its simplest form, the tuning is performed using a light switch or dimmer; in more complex configurations, sensors are used as well as control curves (time lines) and/or control inputs. As a basic requirement, the lighting installation must allow the light sources it incorporates to be varied individually, in groups, or all together. As a minimum, this means the ability to alter the brightness of the light sources but can also include light color and/or spectral composition or even colors. The lighting installation incorporates not only the light fittings (luminaires), operator control units, and control devices but also the blinds or other shading devices which regulate the amount of daylight entering the building. The emergency lighting system can also be integrated. In the case of building management systems, the lighting installation is linked up with other automated services such as heating, ventilation, and air-conditioning.

This type of integrated lighting control is often referred to as lighting management. The purpose of lighting management is to provide the right light in the right place at the right time [1–3].

Overview

The usefulness of lighting control is easy to understand as tuning the light for a particular purpose is not an invention of modern times. Human beings intuitively seek the ideal lighting situation. They spend their lives alternating between periods of activity and relaxation in keeping with the rhythm of day and night. Over the course of the day and the year, they seek and experience the change and variation of natural light.

The invention of electric light brought with it the advantage of having “brightness at the push of a switch,” available at all times. However, there was also an inherent technical limitation: the ability to tune the electric light was initially restricted

to switching it on and off. Lighting was a static arrangement. Despite the fact that the incandescent lamp was dimmable from the outset, this feature proved difficult in the case of discharge lamps. The first widely used fluorescent lamps as well as high-intensity discharge lamps proved reluctant when it came to dimming. Both the physics of these lamps and the ballasts required to operate them made it difficult to regulate their light output without considerable effort. Merely switching them on and off therefore became the common practice. Switching different groups of luminaires was the only approach that came anywhere near “lighting control.”

In the meantime, the available technology has vastly improved. Today’s fluorescent lamps can be cost-effectively dimmed using electronic ballasts, and in the case of LED light sources, tuning the brightness was never a problem. High-intensity discharge lamps, on the other hand, continue to hold out against straightforward dimming.

Lighting control is attracting a lot of attention and is considered a necessary component of a lighting solution.

The main reasons for using lighting control are as follows:

- *To increase energy efficiency:* Dimming and switching reduce the amount of energy consumed by the artificial lighting. When users want less or no light, the artificial lighting can be dimmed or switched off. And if sufficient daylight is available, this can partially or entirely replace the artificial lighting.
- *To improve the light quality:* The ability to adjust the lighting environment to suit the activity or individual preference ensures optimum light quality. Light can be used to set the scene in interiors and in outdoor areas.
- *To enhance safety:* Emergency lighting can be integrated.
- *To ensure flexibility:* By readdressing the individual luminaires, it is possible to provide a fast and flexible response to changes in organization and work layouts. Individual lighting scenes (moods) can also be programmed and changed.

Applications

Where should lighting control be used? The emphasis will vary depending on the application:

Shops

Intuitive control points invite users to adapt the lighting scenes to suit the activity – ranging from light for working at the cash desk to attractive color changes in the lounge.

Growing awareness of the need to save energy has paved the way for dimmable luminaires in retail spaces. It is possible to enhance the visual impression of merchandise and architecture by coordinating changes in color temperature and luminance. High comfort, great flexibility, and low maintenance are the characteristic features of these controlled lighting solutions. The light spectrum, for instance, can be optimally adjusted to suit the illuminated object without the complication of having to change filters. Using control points, timelines, or daylight-linked management of the artificial lighting, the general illumination can also be gradually changed in line with expected light levels over the course of the day. The staging of merchandise to create strong emotional appeal and surprise effects is achieved with the appropriate static and dynamic lighting scenes. Making use of available daylight not only saves energy but also helps to make zones within an interior particularly attractive.

Façades

The use of LED technology in conjunction with lighting control systems has brought about a revolution in façade illumination. The subtlest of messages can be communicated using media façades. Dynamic façade design in particular is aimed at directing the gaze and conveying information. While ecological discussion focuses primarily on the amount of scattered light in the night sky, avoiding the unnecessary use of light by defining sensible operating hours would seem more important. The ultimate purpose of staging façades with light is to attract attention. It therefore makes sense for façades to be lit up exclusively in the evening and morning hours when greater numbers of people are circulating. This approach enables the

identity of companies and communities to be highlighted, structures outdoor spaces at night, and assists nighttime perception while simultaneously addressing ecological objectives.

Museums

Lighting control ensures that sensitive exhibits are only exposed to light which is absolutely necessary, i.e., the level of luminance or the light color required for good perception or when visitors are present, e.g., using occupancy sensing. On and off times can be defined for specific hours of the day. Blinds control and daylight sensors ensure that exactly the right amount of daylight is admitted to achieve a balance between the needs of architecture, human well-being, preventing harm to exhibits, and saving energy. The emergency lighting is discreetly and safely integrated into the lighting management system which provides central monitoring and ensures reliable visibility in an emergency situation.

Hotels

In hotel rooms, intuitive control points which allow the guest to make selections according to individual preference are the first priority. The guest sets the lighting environment. With convenient control of the blinds, the levels of artificial light and daylight are adjusted to suit different activities and visual needs such as watching TV, putting on makeup, or reading. Dynamic lighting moods, with flexible definition based on timelines, or controlled according to weather situation or time of the day, significantly affect the well-being of the guests, particularly in hospitality or wellness areas. In entrance zones, lighting moods based on the outdoor light can also optimize visual adaptation for arriving guests, giving them security and orientation. Defined lighting scenes in conference areas support the use of different media and enable the appropriate light to be provided at the press of a button.

Health and Care

A homely atmosphere and care activities call for entirely different lighting scenes which are available at the press of a button. Intuitive operating features to suit the age and physical abilities of the

occupants as well as the accessibility of the control units are the key to successful lighting solutions in hospitals and care homes. The amount of light required by the eye increases with age. For precise visual tasks, the artificial lighting can be individually adjusted by care staff and patients. In addition, the aging eye filters out blue light, affecting biological processes such as the internal clock and cycles of rest and repair. This must be compensated at specific times of the day by spending time outdoors or through biologically effective artificial light with high intensity and a high blue light component. The use of timelines in lighting management systems permits this interplay of artificial light and daylight at appropriate times of the day.

Office

Lighting control optimally addresses individual lighting needs depending on the age and visual task. Concentrated work and increasing communication call for entirely different requirements to be met by the lighting concept. Biologically effective artificial lighting components at the right time of day in addition to daylight help the internal clock and raise alertness. Lighting management systems with a high level of automation can achieve maximum energy savings as well as flexibility in the case of office moves, thanks to time management, daylight-linked control, and occupancy sensing. Employees readily accept the technology when it gives them the freedom to alter their lighting environment. This means providing adequate means of control and small groups of luminaires with assigned access.

Industry

Industry offers particularly high potential for saving energy. Long periods of lighting use due to shift and night work as well as a lack of daylight in many work areas and rooms mean that investments in lighting management have short payback times. Lighting management ensures the required flexibility in production areas. New lighting installations have to be overdimensioned in order to take into account the effects of deterioration of the installation over time. This additional energy consumption can be counteracted with

daylight-linked or constant light control which continuously adjusts lamp output in line with the available daylight or length of service. Integrated lighting solutions allow the interaction between different services. Maintenance and monitoring operations are also optimized through the incorporation of emergency lighting. Interfaces to other services ensure the convenient and cost-effective operation of buildings.

Education

New forms of teaching and new media technologies call for flexible room use and frequent adaptation of the lighting situation. Intuitive control units are used to select defined lighting scenes at the press of a button, i.e., for working in small groups or traditional teaching, reduced lighting levels for presentations using LCD projectors, or higher vertical illuminance for blackboards and flip charts. Comfortable control units enable the user to rapidly adapt the lighting situation.

Daylight activates human beings and enhances their feeling of well-being as well as their performance. With daylight-linked control of the artificial lighting or occupancy sensing, it is possible to achieve maximum energy savings without restricting the quality of light. Blinds control not only improves the contrasts of presentation media but also increases room comfort because glare and heat gain can be minimized. Conveniently placed control units near the door and on the teacher's desk enable intuitive selection of the appropriate lighting situation.

Corridors and Stairways

Circulation zones are predestined for lighting management. Ideally, the lighting should only be activated if a person approaches. The light should be on once the person has entered the circulation zone. Movement detectors must be suitably positioned. The energy consumption of lighting in corridors and stairways can be further reduced in conjunction with daylight-linked control.

Streets and Public Spaces

Illumination is necessary for reasons of safety and orientation in streets and public spaces. Switching the lighting on and off in conjunction with the

available daylight has long been a common practice. Nowadays, it is also possible to reduce brightness levels at hours of the night when traffic density decreases. Control is performed centrally for streets, districts, and public spaces.

Movement detectors can be installed to ensure that the brightness of the lighting anticipates the approach of pedestrians and cyclists. While the general brightness level is lowered, it can be increased at the point of use to ensure safe circulation.

Domestic

Being able to vary the lighting takes on particular emotional importance in the home setting. Well-being and work, social interaction, and intimacy all take place within the confines of a small space. Access to different lighting moods at the press of a button enables the occupants to set the scene for their private space with area, accent, and mood lighting. Blinds are frequently integrated into the control system to regulate solar heat gain. Time control is also a security feature which can be used to make the house appear occupied when the residents are away on holiday.

Individual lighting scenes can be selected from a central control panel. Switches incorporating a reduced number of scenes on doors and in readily accessible locations allow intuitive operation of the lighting installation.

The possibilities and the requirements of the application are taken into account in the lighting concept. The lighting designer incorporates the operator control units, the control devices, and the choice, number, and arrangement of luminaires, blinds, and other actuators.

Interfaces for Lighting Management

Generally, there are interfaces between the user, the environment, and the lighting installation.

The user can actively intervene using different operator control units:

- *Standard or momentary action switch, with or without dimming function:* The simplest form is a switch and/or dimmer frequently fitted near

the door or in another readily accessible location in the room.

- *Multifunction switch*: Also near the door or in a readily accessible location, for calling up different lighting scenes.
- *Remote control*: This can be an IR or wireless unit or the user's mobile phone, for calling up individual lighting scenes.
- *Workstation control*: In this case, operation is through the user's own computer or using a control unit directly at the workstation.
- *Central control unit*: At a defined location, trained personnel can select specific scenes or timelines for the lighting installation, often using a touch screen.

The environment can be integrated by means of sensors or defined timelines:

- *Daylight sensors*: Sensors installed outdoors or near daylight openings detect the level of daylight brightness and transmit the appropriate signals to control or regulate the lighting installation (luminaires and blinds).
- *Presence or absence detectors*: These sense whether there is a person within their detection zone. The signals they transmit switch the lighting installation on or off.
- *Time signals*: The lighting can be switched to preselected scenes at set times. The simplest case is to switch off all the lights at specific times. It is also possible to call up timelines to automatically tune the lighting in accordance with programmed strategies.
- *User behavior sensors*: Signals based not only on presence or absence but also on user movement patterns can be used to initiate situation-based tuning of the lighting situation.
- *Environmental signals*: Other predefined data can be used for control purposes, e.g., to maintain constant luminous flux on the basis of set maintenance factor curves or to reduce installation output if the energy demand exceeds a specific limit.

Behind each operator function, there are signals which are processed by the lighting management system. This means, for instance, that if a

sensor detects that a person has left the room, switch off can be delayed.

Intelligent control is based on the following logic: for each activity, a lighting scene is defined, saved, called up, and modified as required. Each scene is assigned a name and a symbol which are shown on the operator control units. The lighting scenes are activated automatically by means of presence detectors or simple time inputs. The basic philosophy is always the same: it must be possible to manually override any activated lighting scene.

Strategies for Lighting Management

What strategies can be used to achieve useful objectives with a lighting management system? Firstly, those objectives have to be defined, and, secondly, acceptance of the usefulness of the objectives put to the test.

One objective is to increase energy efficiency:

1. Individual switch on and off: This simplest objective is dependent on a switch being located near the user. Users appreciate this possibility but frequently do not use it.
2. Daylight-linked control – switching function: Automatic switch on and off; the control input is the daylight measured by a sensor.
3. Daylight-linked control – switching function: Automatic switch off and manual/individual switch on; this requires a daylight sensor and a switch.
4. Daylight-linked control – dimming: Automatic setting at a constant value; the control input is the daylight measured by a sensor.
5. Daylight-linked control – dimming: Automatic switch off and individual switch on; this requires a daylight sensor and a switch.
6. Occupancy-based control – switching function: Automatic switch on and off; the control input is delivered by a sensor which detects human presence.
7. Occupancy-based control – switching function: Automatic switch off and individual switch on; this requires a presence detector and a switch.

8. Constant light control (without daylight): A constant level of luminous flux is maintained to compensate for the decrease in light output with increasing age of the installation; the control input is delivered by a programmed timeline or a sensor for the emitted luminous flux.
9. Time-based control: Programmed lighting scenes are called up, and the installation is switched on or off at set times.
10. Load shedding: Automatic limitation of energy demand.

Another objective is to improve the quality of light:

11. Activity-related control: Individual setting of a lighting scene to suit an activity; this includes the switching and dimming of individual blinds, luminaires, and groups of luminaires in the adjacent area.
12. Individual daylight control: Individual operation of blinds to avoid disturbances such as glare and heat.
13. Automatic daylight control: Automatic control of blinds to reduce heat gain and glare from direct sunlight and excessive outdoor brightness; this requires a daylight sensor.
14. Algorithmic lighting: Automatic sequence of variations in the lighting based on programmed rules.
15. Room-related scene setting: Selection of pre-set static or dynamic lighting scenes.

User Acceptance and Energy Efficiency

While the various strategies might bring great benefits from a planning perspective, they also have to be accepted by the users. Many field studies have looked at the question of user acceptance.

One of the essential requirements is the ability to manually override each activated lighting scene. In comparison with automated processes, however, this makes it difficult to calculate the parameters for possible energy savings, the determination of which is a major challenge in view of the many unknown factors.

The behavior of energy-conscious occupants receives too little attention in calculations of this kind. Making the groups of luminaires as small as possible provides greater opportunity to change the lighting situation manually and individually to suit requirements. Large rooms with several groups of luminaires do not lend themselves to this approach as it is difficult for large numbers of users to agree the preferred setting of the lighting installation. For this reason, a smaller group of luminaires and operator control units must be installed in close proximity to enable the user to make spontaneous changes.

Changing weather conditions and unforeseeable user behavior make it difficult to predict energy usage. The time delay for presence detectors also plays a role.

In view of their complexity, the dynamic changes taking place in the world of work and in building use are continually being analyzed and measured in field studies carried out by different industries. In the context of a lighting management system, human behavior will always be more difficult to predict than technically defined parameters (Table 1).

Technical Requirements

The transmission of information from the operator control units and control devices to the actuators is at the heart of any lighting management system. Actuators are luminaires, blinds, or other equipment integrated into the lighting management system.

Information transmission means the sending and receiving of signals, which can be achieved using various means:

- The signal “on/off/dim” is sent via the power line.
- Signal transmission between operator control units and control devices takes place using the power line.
- Signal transmission between operator control units and control devices and to the powered luminaire/actuator uses a separate control line with standardized control signals (DALI, DMX)

Lighting Controls, Table 1 The table shows the effect of individual strategies on energy efficiency and light quality and assesses the associated user acceptance

Strategy	Operation	Energy efficiency	Light quality	Acceptance
1. Individual		Low	High	High
2. Daylight-linked control – switching	Auto off, auto on	Medium	Medium	Low
3. Daylight-linked control – switching	Auto off, manual on	High	Medium	Medium
4. Daylight-linked control – dimming	Auto off, auto on	High	Medium	Medium
5. Daylight-linked control – dimming	Auto off, manual on	Very high	Medium	High
6. Occupancy-based control – switching	Auto off, auto on	High	Medium	Medium
7. Occupancy-based control – switching	Auto off, manual on	Very high	Medium	High
8. Constant light	Auto	High	Medium	Medium
9. Time-based control	Auto	Very high	Medium	High
10. Load shedding	Auto	High	Medium	Medium
11. Activity-related control	Manual	Medium	Very high	Very high
12. Individual daylight control	Manual	Medium	High	Very high

Auto automatic

- Operator control units and control devices (e.g., computers) are networked via data lines. Communication is by means of bus (LON, KNX, Luxmate, etc.) or TCP/IP protocols.

Definitions

Bus protocols such as LON, KNX, and Luxmate: Bus systems network all technical services in the building and provide central control for heating, ventilation, window blinds, and security systems.

TCP/IP: Transmission Control Protocol/Internet Protocol (TCP/IP) is the set of communication protocols used for the Internet and is consequently also referred to as the Internet protocol suite.

DALI stands for Digital Addressable Lighting Interface and is a standardized digital interface for control gear and electronic ballasts. DALI can be used with a small number of lines to address large numbers of control circuits over large distances.

DMX is an acronym for Digital Multiplex, a standard for digital communication networks commonly used to control stage and event lighting. Nowadays, the DMX protocol is also frequently used by architects and lighting designers as it enables over 500 channels to be controlled individually with rapid signal sequences from a single central control unit.

Luminaires, blinds, and other actuators integrated into the lighting management system have to be compatible with the existing communication protocols and understand the signals. The actuators are assigned individual or group addresses so that they can be uniquely identified within the network and to enable them to communicate.

In the case of classic lighting installations equipped with fluorescent lamps, dimmable ballasts have to be used. High-intensity discharge lamps, on the other hand, can rarely be dimmed, at best switched in stages. As a rule, LED lighting incorporates dimming. With relatively simple means, it also offers the opportunity to vary the light color (with a range from 2,700 to over 8,000 K) or even to set different colors using RGB diodes.

Lighting Design

The decision regarding a lighting management system should be made at an early stage of the project. Lighting management is an integral part of the overall building management system. For this reason, the lighting management system will

often come under a different budget to the actual lighting installation itself.

The choice and layout of the luminaires should allow different lighting scenes to be selected.

The location of operator control units, the layout of the luminaires, and in particular the integration of daylight should be part of a holistic design approach. Service and long-term support for the lighting management system will ensure that the operators obtain the expected benefits.

Factors Driving Lighting Management

The growing demands for lighting installations to be energy efficient are currently a strong driver for the use of lighting management. European green building directives are leading to national regulations for energy requirements in buildings, which cannot be met without the use of lighting management. Daylight-linked control and presence detectors are therefore a necessity.

Green building certification schemes also look to reduce environmental impact with the aid of intelligent lighting management. Well-known schemes include LEED, BREEAM, DGNB, and CASBEE, among others. As well as helping to reduce energy consumption, the integration of lighting management can improve the quality of light for the users.

Synonyms

[Lighting for visual comfort](#)

Definition

Lighting that makes the overall appearance of a lit interior space being experienced as visually

satisfying. Here visual satisfaction relates to such aspects as spaciousness, attractiveness, relaxedness, intimacy, and worker's stimulation.

Room Appearance

The visual appearance of a room determines for an important part whether the lighting has a positive impact on persons in that room. Most of the psychophysical studies that have demonstrated this relate to office type of spaces. These studies try to relate subjective aspects with the luminance and luminance distribution of the surfaces in the space. For this purpose test persons assess a large number of different lighting situations, usually in test rooms under laboratory conditions. The

lighting of the room boundaries determines, to a large extent, the room appearance as a whole. The classic assessment study of room boundary surfaces is that of Loe et al. [1]. The full-scale mock-up office room used for the experiments (Fig. 1) was furnished as a small conference room.

Eighteen widely different lighting situations were assessed by observers from a fixed position in the middle of the long side of the room. Lighting varied in both lighting level and lighting distribution. Detailed luminance measurements of all room surfaces were made for all lighting situations. From these, the average luminance, L_{av} , and luminance uniformity expressed as L_{max}/L_{min} were calculated for the whole area, for the areas represented by circles subtending an angle of 20° and 40° , respectively, and for horizontal bands

Lighting for Visual Satisfaction, Fig. 1 Mock-up conference room with different dominant areas that were investigated by Loe et al. (1994)

with a width of 20° and 40°, as illustrated in Fig. 1. The 20° circle and band normally only include wall surfaces, while the 40° circle and band, for larger rooms, also include part of the floor and ceiling surface. This becomes clear by comparing the small room, sketched with a broken line at the bottom of Fig. 1, with the larger room drawn in a full line. The subjective aspects assessed can be brought together under two factors. The first factor, “visual lightness,” covers the interrelated subjective aspects of “bright–dim,” “radiant–gloomy,” and “spacious–cramped.” The other factor, which can be labeled as “visual interest,” includes the aspects “nonuniform–uniform,” “interesting–uninteresting,” “pleasant–unpleasant,” “stimulating–subdued,” and “dramatic–diffuse.” The factor “visual lightness” appeared to correlate best with the logarithmic value of the average luminance of the band with a width of 40°, i.e., the B40 band (Fig. 2). The factor “visual interest” correlates best with the logarithm of the uniformity ratio $L_{\max}/L_{\min}$, again of the B40 band (Fig. 3).

Twenty years later, Kirsch [2] made a visual lightness assessment study in a cell type of office mock-up. The walls and ceiling consisted of back-lit (3000 K) diffuse acrylic panels that could be dimmed separately to generate many different room surface luminances. The small squares in Fig. 2 give the results. They are in good agreement with the earlier results of Loe et al. Kirsch also checked the chronotype of his test persons. He showed that there is a significant difference between morning and evening chronotypes. Morning types require in the evening higher luminances than in the morning for the same assessment of brightness. With evening types it is just the other way around: they need in the morning higher luminances than in the evening. At the midpoint, the difference is around 20 cd/m^2 .

The small squares in Fig. 3 give the results of Kirsch for luminance uniformity. The thin broken-line curve in Fig. 3 is the best trend curve when the results of Loe et al. and Kirsch are combined. The relationship that this curve suggests makes sense. Uniform room luminance distributions lead to an

Lighting for Visual Satisfaction, Fig. 2 Bright–dim assessment, being representative for the factor “visual lightness,” as a function of the average luminance $L_{\text{av},\text{B40}}$ of the B40 band [1, 2]

Lighting for Visual Satisfaction, Fig. 3 Visual interest as a function of the ratio $L_{\max}/L_{\min}, B40$ of the B40 band [1]. The results for the appraisal attractiveness [2] are given on the same assessment scale

appraisal “uninteresting” and “unattractive.” The more nonuniform the situation becomes (larger $L_{\max}/L_{\min}$ ratio), the more interesting and attractive lighting is appraised until the maximum appraisal is obtained. From that situation onward, the appraisal decreases with a further increase in nonuniformity until it becomes unacceptable.

By calculating the average luminance and luminance ratio for the B40 band, it is possible to evaluate lighting designs with the aid of Figs. 2 and 3, for each specific observer position and each viewing direction.

Directionality and Modeling

The directionality of lighting relates to the difference in intensity with which the light is incident on objects from different directions. It determines the appearance of three-dimensional objects and faces of persons in space. A too low degree of directionality (and thus a high diffuseness) gives soft or no shadows, which results in a dull environment in which identification of objects and faces is difficult. Too strong directionality produces harsh shadows

in which details of the object are hidden, making the object appear unattractive and difficult to identify. The modeling effect of lighting is good when it reveals the details and texture of objects and results in an aesthetically pleasing environment. The balance between the diffuse and directional components of a lighting installation determines the quality of directionality.

Flow of Lighting

To mathematically study the effect of light on objects in space, Gershun [3] introduced in 1936 the expression “light field” and visualized it with “flow lines.” Cuttle et al. [4] introduced a promising and practical concept, which they called “flow of lighting.” This concept allows for the calculation of the main direction and strength of the light at a point in space as a result of all light rays at that point. Cuttle showed that flow of lighting could be quantified by the so-called vector-to-scalar ratio, $E_{\text{vector}}/E_{\text{scalar}}$ [4–6]. It contains two measures, the illuminance vector and scalar illuminance. The illuminance vector characterizes the direction and magnitude of the light flow at a point in the lit space. The final directional

Lighting for Visual Satisfaction, Fig. 4 Left: The illumination vector at a point is defined by that (infinitesimally small) disk having the largest difference in illuminances on the opposing sides of the disk. The vector is directed away

from the side having the lowest illuminance. Right: The scalar illuminance is the mean illuminance on the surface of an (infinitesimally small) sphere

effect of it depends on the ambient or overall lighting at that same point. The higher the overall lighting at a point is, the lower the directional effect. The scalar illuminance (E_{scalar}) at a point characterizes the overall illumination at that point. It is the mean illuminance on the surface of an (infinitesimally small) sphere at that point (Fig. 4, right). It is also called mean spherical illuminance. The maximum difference in illuminance between opposite sides of an (infinitesimally small) flat disk at a point defines the magnitude of the illuminance vector (E_{vector}) at that point (Fig. 4, left). The direction of the vector is defined by the orientation of the disk for which the maximum difference is obtained. It is the direction of the normal to the disk surface at that orientation, away from the side having the lowest illuminance (Fig. 4, left).

With no directionality of lighting, the vector/scalar ratio is zero, and the maximum value is 4, which is the case in a situation with a single parallel light beam in a complete black interior. Table 1 gives vector/scalar ratio values with corresponding appearances and suggested applications as proposed by Cuttle.

Light Tubes

The flow of lighting can be visualized by so-called light tubes [7]. Light tubes are a further

development of the earlier mentioned flow lines of Gershun. The direction of a light tube is in each position parallel to the light vector, while the opening width of the tube is inversely related to the magnitude of that vector. This magnitude is equal to the average light flux “flowing” through the tube at that position. It means that at locations where the tube is small and the magnitude of the vector is large, the net light transport is large (high flux density). Near to light sources, from where the tubes originate, they are small (large flux transport). The tubes end up on the room surfaces, where the net light transport has become small, and the tubes consequently are wide. Light tubes are not the same as light rays and can, therefore, contrary to light rays, be curved. Light tubes are based on the combined effect of all light incident at a point from all directions (from both direct and indirect contributions). Figure 5 illustrates the difference between light rays and light tubes.

With today’s available computer graphic software, methods for light tube visualizations of complete lighting installations have been developed [7–12]. This type of visualizations allows a detailed analysis of the spatial and form-giving potential of lighting designs. It combines two early concepts, “lighting field” (Gershun [3]) and “flow of lighting” (Cuttle et al. [4]), into a modern tool for the professional lighting designer.

Lighting for Visual Satisfaction, Table 1 Vector/scalar ratio with appearance effect and application suggestions (Cuttle [6])

$E_{\text{vector}}/E_{\text{scalar}}$	Appearance	Application
4.0		
3.5	Dramatic	Strong contrasts, details in shadows not discernible
3.0	Very strong	Suitable for displays, too harsh for human features
2.5	Strong	Pleasant appearance for distant faces (formal)
2.0	Moderately strong	Pleasant appearance for near faces (informal)
1.5	Moderately weak	Soft lighting for subdued effects
1.0	Weak	Flat shadow-free lighting
0.5	Very weak	
0

magnitude of the vector. Top, large illumination vector and corresponding small light tube; bottom, smaller illumination vector and corresponding wider light tube

Discomfort Glare

Glare can take either of the two forms: disability glare and discomfort glare. Disability glare is the form that is responsible for the negative influence of glare on visual performance. Disability glare

has a neglectable effect on visual performance under most interior lighting conditions [13]. Glare that causes a feeling of discomfort is referred to as discomfort glare. It can cause problems in interior lighting situations. The discomfort effect of glare may lead to feelings of irritation and

fatigue. The eyes may contract. In extreme circumstances, discomfort glare may result in painful feelings and after prolonged exposure in headaches. The adverse effects of discomfort glare vary to a great extent in type and seriousness between persons.

The physiological and psychological mechanism underlying discomfort glare sensations is not yet clearly understood. Bargary et al. [14] studied functional magnetic resonance imaging (fMRI) scans of the brain produced in the presence of discomfort glare. Their results suggest that the physiological properties of receptive fields and their ON-OFF center-surround ganglion cells may play a fundamental role in evoking discomfort glare sensations. Donners et al., Scheir et al., and Safdar et al. [15–18] use as a basis for their discomfort glare considerations the neural response to bright light and the mechanism of receptive fields. These studies demonstrate that models built upon center-surround receptive fields and their ganglion cells that transform luminance signals into edge detection signals are promising candidates for quantifying discomfort glare from a physiological point of view. Until a generally accepted fundamental approach, based on the mechanism underlying discomfort glare sensations, results in a workable method to quantify discomfort glare, empirical studies form the background for the metrics used to quantify discomfort glare.

In 1995, CIE combined the best parts of the different, empirically derived, glare evaluation methods in use at that time into one formula. Because of this “consensus method,” the result is called “CIE Unified Glare Rating (UGR)” [19]. This method, recently slightly adapted to make it also suitable for LED luminaires with an irregular light-emitting surface luminance [20], is still in use today for the restriction of discomfort glare caused by artificial lighting in interiors. It is described in more detail in this encyclopedia under the entry “Glare.”

Light Color Preference

Research on preferred correlated color temperature for general lighting in interiors gives conflicting results. Kruithof was the first who did

a study, already in 1941, on the relationship between correlated color temperature and appraisal of the pleasantness of lighting [21]. Up to the present day, his study is often used as a reference. With all the knowledge gathered since Kruithof carried out his tests, the conclusion can only be that his conclusions are not valid for general use. The entry “Kruithof Curve” in this encyclopedia gives a more detailed description of the subject.

Linguistic Relativism

► Color Category Learning in Naming-Game Simulations

Lippmann, Jonas Ferdinand Gabriel

Mark D. Fairchild

College of Science, Rochester Institute of Technology, Rochester, NY, USA

Gabriel Lippmann was a French inventor and physicist (born in Luxembourg) who created the first color photographs using what was certainly the first spectral imaging system. Lippmann's system of color photography was conceived in 1886 and then refined for several years due to the complex nature of its theory and implementation. The system works by placing a very fine-grain photographic plate in contact with mercury that acts as a mirror. Light waves pass through the emulsion, reflect from the mercury backing, and then create an interference pattern within the emulsion. The developed plate then has an interference filter built into it due to the properly spaced layers of silver in the emulsion (created by the interference pattern exposure). The plates are then viewed with directional lighting, and the observer sees the same wavelengths that were present in the scene – a spectral image reproduction. Lippmann presented

the first color photograph using his system in 1891 and then presented several nearly flawless photographs made by Auguste and Louis Lumière created with the process. The process was difficult and time-consuming, and few have been able to replicate the stunning photographs. Lippmann's work certainly presaged modern photographic and holographic processes, and for it he received the 1908 Nobel Prize in Physics.

Despite ending up a full professor at the Sorbonne (University of Paris), Lippmann had no formal education beyond high school. He was a student at the École Normale, but failed the examination that would have qualified him as a teacher due to his penchant for concentrating only on the work that interested him and neglecting the rest. However, he was appointed to a government scientific mission to Germany where he was able to work with the likes of Kirchhoff and Helmholtz. At about the same time, in 1873, he invented the Lippmann capillary electrometer for precise measurements of extremely small electrical voltages. It served as the basis for early echocardiographs. Lippmann joined the Faculty of Science in Paris in 1878, became Professor of Mathematical Physics in 1883, and was later appointed Professor of Experimental Physics and Director of the Research Laboratory. He made many contributions in various fields of physics including electricity, thermodynamics, optics, and photochemistry.

In addition to his Nobel Prize for the Lippmann process of full-color photography, Gabriel Lippmann served as Marie Curie's thesis advisor at the Sorbonne and let her use his laboratory for her thesis work in radioactivity and helped her find other sources of support. Lippmann died at sea in 1921 while returning from a voyage to Canada. There is no record of the cause of death.

Lippmann's Nobel lecture on color photography can be found at the following link:

Lovibond, Joseph Williams

Mark D. Fairchild

College of Science, Rochester Institute of Technology, Rochester, NY, USA

Joseph Lovibond was a British chemist and brewer and is credited with inventing the commercial colorimetry, the Lovibond Tintometer. In Lovibond's *Light and Colour Theories* [1], we read "the writer was formerly a brewer, and this work had its origin in an observation that the finest flavour of beer was always associated with a colour technically called 'golden amber,' and that, as the flavour deteriorated, so the colour assumed a reddish hue." Such observations of the relationships between beer quality and observed color led

Lovibond to his work on color standards as a reliable means of reference and to the development of an instrument, the visual colorimeter, in which such standards could be systematically and objectively applied.

The general form of the Lovibond Tintometer was a visual colorimeter in which a split field is viewed. One half of the split field represented the test sample, perhaps a cuvette of beer placed in a beam of light. The other side of the split field was composed of subtractive primaries of adjustable density (e.g., a series of cyan, magenta, yellow, and neutral glass filters) that could be adjusted to select the density and overlapped one another in the adjacent beam of light. By adjusting the density of the filters, observers would match the test color stimulus and record the densities of the standard filters required for the match. Note again that the Tintometer system was one of subtractive color mixing of standard materials rather than the more common additive color mixing of standard lights typically found in visual colorimetry.

While brewing beer might have been the motivation for the Tintometer, by 1914, the system was in use in a wide variety of additional industries including tanning, wine and spirits, dyeing and printing, paint, water chemistry, ceramics, various oils, and hematology. In many cases, specific versions of the instrument and the reference standards were produced for a given application. The system was also presented with a number of awards by international juries (including two gold, five silver, and two bronze medals) along with significant recognition from ten scientific societies (one gold, three silver, and five bronze medals and a diploma). Lovibond worked tirelessly in promoting his system through lectures and demonstrations around the world. He created a technically successful system that also met with commercial success. In fact, The Tintometer Limited still exists to this day with products such as color standards and scales, visual colorimeters (including versions of the Lovibond Tintometer), and photoelectric colorimeters and spectrophotometers. For example, one can still purchase instruments and standard color scales designed

for American (ASBC) and European (EBC) methods of specifying beer color. Lovibond's initial inspiration is still being addressed by the progeny of his instruments using his very techniques.

In the history of The Tintometer Limited, it is stated that "The Company was founded in 1885 by Joseph Lovibond, a prominent brewery owner who developed the 'colorimeter' as a means of ensuring the quality of his beer. By 1893 he had perfected his research and introduced the first instruments. Much has developed since then. Today, the company is bringing colour measurement to the next generation. While still recognizing the importance of traditional methods, The Tintometer Ltd is introducing new techniques to bring measurement and quality control to an even higher level, developing creative solutions to ensure the continued reputation of the Lovibond® brand" [2].

Low-Pressure Glow Discharge Lamps

► Neon Lamp

Lumen Depreciation

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Light depreciation](#)

Definition

Light losses during the use of a lighting installation, caused by the decrease of the luminous flux of lamps, the dirt accumulation on and loss of reflectivity and/or transparency of luminaires, and dirt accumulation on or discoloration of room surfaces (in interiors).

Lamp Lumen Depreciation

The light output of virtually all lamp types declines gradually during operation. The causes of light output depreciation are numerous. With incandescent lamps, it is mainly the blackening of the bulb – caused by evaporation of the filament. Discharge lamps also suffer from blackening, in this case, due to scattering of the electrode material, which settles on the wall of the discharge tube. With fluorescent lamps, high-pressure mercury lamps, and solid-state LED and OLED light sources with a fluorescent coating, the primary cause of light output depreciation is a gradual exhaustion of the fluorescent powder, which slowly loses its effectiveness.

Because of the different causes of lamp lumen depreciation, the actual rate of decline of lumen output is different per lamp type. Lamp manufacturers should be able to supply lamp lumen depreciation curves for their lamps.

Lumen Depreciation and Lifetime of LEDs

Quality non-retrofit LED light sources have nowadays such a long life, 50,000 hours and longer, that it is not the failure rate that determines how long the LED light source continues to provide lighting up to specification. It is in particular the LED parameters “lumen output” and “color quality” that determine operational life. When the value of one of these parameters becomes so low that the LED light source has to be replaced, that LED source has a so-called parametric failure, although the LED source may continue to

function for a much longer time. The moment at which the LED light source completely stops functioning is referred to as an abrupt or catastrophic failure.

The International Electrotechnical Commission (IEC) defines in its standard “LED modules for general lighting – Performance requirements” [1], LED lifetime by the parametric failure: “too low lumen output.” This lifetime is specified as Y hours useful life based on the condition Lx B50. Here Y is the time (in hours) after which 50% (B50) of a population of LED modules parametrically fails to provide at least a percentage x of the initial luminous flux. Which lumen depreciation percentage is relevant is dependent upon the type of application. L90B50, L80B50, and L70B50 are values that may be relevant. The L70 condition is often used as corresponding to “the lifetime” of a LED source. However, for quite some applications, a lumen maintained value of 70% is too low and requires unneeded high new lighting values to be installed. Just using L70 increases the chances of specifying low-quality products. High-quality products with long lifetime values corresponding to L80 or L90 conditions are often more cost- and energy-effective. It is important to stress that lifetime specifications without indication according to which Lx condition are senseless. According to IEC the value of B always has to be 50, meaning that 50% of a set of LEDs of the same type failed to deliver the declared percentage x of lamp lumen, i.e., B50. If only the Lx value is given, B is assumed to be 50.

An essential point in the IEC standard is that it considers failures of single LEDs in a multi-LED module to contribute to the gradual lumen output degradation. The effect is incorporated in the lamp lumen depreciation and thus in the Lx condition. Abrupt, catastrophic, complete failures of a LED module are referred to as Cz: length of time during which z% of a population of LED modules of the same type fail to produce any luminous flux. Figure 1 gives typical examples of different LxBxCz conditions for a LED module.

An accurate prediction of the percentage of abrupt complete failures Cz over the very long lifetime of LEDs is practically not possible. It is

Lumen Depreciation,

Fig. 1 Examples of different LxByCz conditions of a LED module

also not so important because, as discussed, it is the lamp lumen depreciation, and thus Lx, that determines the useful life of LEDs.

The industry standard for lumen maintenance testing of a batch of LEDs is a document of the Illuminating Engineering Society of North America, “IES Document LM-80, Measuring lumen maintenance of LED light sources” [2, 3]. IEC [1] refers to these documents for the testing of lumen maintenance of LED light sources. The LM-80 document prescribes the LED sampling method, the laboratory environment conditions, the photometric measurement protocol, and the operating conditions (electrical and thermal) of the LEDs to be tested.

Tests according to document LM-80 provide no lifetime of the LED type tested. The data obtained are the input for another IES report that predicts through interpolation of the LM-80 data, useful life. This second IES document, TM-21 “Projecting long term lumen maintenance of LED light sources” [4], describes a mathematical interpolation method, using data obtained with the test described in LM-80. It permits for a prediction of the lumen maintenance percentage at a life six times that of the tested period (based on a minimum sample size of 20 pieces). More extended predictions are unrealistic because of limitations

in the extrapolation and lack of confidence in the data beyond. A more recent addendum of TM-21 stresses again that calculated (interpolated) results beyond the limit of six do not have a practical or meaningful value [5]. For an LM-80 tested period of 6000 h, this corresponds to a prediction for maximum 36,000 h. For a tested period of 10,000 h, the prediction is for maximum 60,000 h.

Luminaire Depreciation

The gradual reduction of output of a luminaire is caused by dirt that is gradually deposited on lamps and on or in the luminaires and by a gradual loss of reflectivity of reflectors and mirrors or loss of transparency of refractors due to corrosion and discoloration. Where the effects of dirt accumulation can be offset by regular cleaning, the output loss due to corrosion and discoloration cannot be regained. The rate of output reduction depends on the materials used in the luminaire, the construction of the luminaire, and the nature of airborne dirt in the atmosphere. The degree of protection provided by the construction of the luminaire is classified according to the international protection code, IP, as described in an international IEC standard.

Room Surface Depreciation

Gradual dirt collection on room surfaces and/or discoloration of these surfaces gradually reduces the interreflected component of light from the installation. This may especially have a noticeable effect in interiors of smaller dimensions where, because of the relative large wall area, interreflection components are relatively large.

Maintenance Factor

The maintenance factor is the ratio of illuminance or luminance produced by the lighting installation at the moment that maintenance operations are being carried out to the illuminance or luminance produced by that installation when new. The maintenance factor takes into account all light losses described above together with the average light loss of the installation due to failed lamps not being replaced. The actual value is, of course, also dependent on the length of the period between maintenance operations. The term light loss factor has sometimes been used instead of maintenance factor. Depreciation factor has been formerly used to designate the reciprocal of the above ratio.

The recommended lighting level (in terms of illuminance or luminance) for a lighting design is based on “maintained lighting level” which is the average lighting level at the moment that maintenance is being carried out. This implies that the initial lighting level has to be:

$$L_{\text{initial}} = L_{\text{maintained}} / \text{Maintenance factor}$$

It is the responsibility of the lighting designer to make an economical balance between the recommended length of the maintenance interval and the extra light required for the initial installation. Shorter maintenance intervals increase the maintenance cost but allow for lower initial lighting levels with a lower initial investment and lower energy costs.

Luminaires

Wout van Bommel

van Bommel Lighting Consultant, Nuenen, The Netherlands

Synonyms

[Fitting](#) (Anglo-Saxon English); [Fixture](#) (American English)

Definition

Devices that control the distribution of the light emitted by a lamp or lamps and that include all the items necessary for fixing and protecting the lamps (and sometimes the gear, too) and for connecting them to the electricity-supply circuit [1].

Luminaire Characteristics

The principal characteristics of luminaires can be listed under the following headings:

- Optical
- Mechanical
- Electrical
- Thermal
- Aesthetics

Optical Characteristics

The optical characteristics of a luminaire determine the shape of its light beam or light-output distribution. The light distribution of a luminaire defines how the luminous flux radiated by the lamp or lamps is distributed in the various directions within the space around it. Different lighting applications require different light distributions and thus different luminaires.

The desired light distribution of a luminaire is obtained through the application of one or more of the physical phenomena: reflection, refraction, and diffuse transmission. Many luminaires also make use of shielding in one form or another, principally to obtain the required degree of glare control and to limit light pollution. The shielding function may be performed by refractors or diffusers or by mirror reflectors, by white-painted surfaces, or, where very stringent glare control is required, by black surfaces.

Reflectors

Many conventional luminaires are provided with a reflector (sometimes in conjunction with another light-control element) in order to create the appropriate light distribution. The reflecting material that is used for reflectors can be specular, spread, or diffuse.

Specular Reflectors

Specular reflectors (also called high-gloss mirror reflectors) are used when a precise form of light distribution is required, as in floodlights, spotlights, and road-lighting luminaires. The reflector creates multiple images of the light source. The most widely used material is sheet aluminum, which has the strength needed to produce a stable reflector. Reflectance values are around 0.70. Alternatively, commercial-grade aluminum can be clad with a thin layer of super-purity aluminum or silver. With aluminum, reflectance values of up to 0.80 can be obtained, while with silver a reflectance of more than 0.90 is possible. Finally, there is vacuum metalizing, in which a specular layer of aluminum is deposited on a suitably smooth

substrate (metal, glass, or plastics). The resulting reflectance, which is somewhere between 0.80 and 0.90, is dependent on both the substrate material and the quality of the metalizing process.

Spread Reflectors

With spread reflectors (sometimes also called half-matt reflectors), there is no sharp mirror image of the light source. They are employed where a moderate degree of optical control is required, with the emphasis on producing a beam with smooth transitions. Such reflectors also help to smooth out discontinuities in the light distribution caused by inaccuracies in the shape of the reflector. Spread reflection is produced by brushing or etching or by hammering very small dimples and bumps into a specular surface (Fig. 1).

Diffuse Reflectors

At the other extreme from specular reflection is the diffuse reflection, which is also called matt reflection. Here light incident on the reflector is scattered in all directions, so there is no mirror image of the light source. Matt reflectors cannot provide sharp beam control but are employed where diffuse or non-focused light distributions are required. Matt-finished metals and glossy white paints on metal or glossy-white plastics provide near-diffuse reflection. The small specular component due to the gloss is of no practical optical significance; the gloss merely serves to facilitate cleaning. Reflectance values can be in the range 0.85–0.90. Ceramic materials or finishes have completely diffuse reflection characteristics with extremely high reflectances of up to 0.98.

Reflector Forms

There are three basic reflector forms: plane, curved, and faceted (Fig. 2).

Plane Reflectors

When using a simple plane (or straight-sided) reflector, the light emitted by the light source is reflected according to the material of the reflecting surface, viz., specularly or diffusely.

Plane reflectors are often used to screen off the direct light from the light source. Accurate beam

Luminaire, Fig. 1 A spread finish as produced by brushing (*left*) or by hammering (*right*) a specular surface

Luminaire, Fig. 2 Basic reflector forms

shaping is scarcely possible with plane reflectors, but by changing the symmetry of the reflectors, the direction in which the bulk of the light is emitted can be changed.

Curved Reflectors

The best optical performance is obtained when using a curved reflector. Depending on the curvature, many different types of beams can be created. A curved reflector may be cylindrical, parabolic, elliptical, hyperbolic, or some other contour to suit a particular application. The circular and parabolically shaped reflectors are the ones most commonly used.

The most important optical property of a parabolic reflector is that a point source of light placed in its focus will produce a parallel beam of reflected rays with the highest intensity in its center. If the light source is not at the focus but in front or behind it, the reflected rays are no longer parallel. Thus, by choosing the position of the light source relative to the focus point, the desired beam shape (narrow to wide) can be

created. Since a lamp is never a real point source, deviations from the theoretical beam shape for a point light source as sketched above will always occur. The smaller the light source relative to the size of the reflector, the more accurately can the beam be shaped.

Faceted Reflectors

Smooth-curved reflectors have to be produced to a high degree of accuracy because even small deviations from their intended shape will produce undesirable discontinuities in their light distribution (striations). This will not occur with a faceted reflector. A faceted reflector consists of a number of adjacent, plane or curved, facets that together approximate a curve that is an approximation of a parabolic curve. The width of beam produced by the faceted reflector is somewhat larger than that of a smooth-curved reflector.

Total Internal Reflection Optics

The phenomenon of total internal reflection (TIR) on the boundary between an optical medium and

Luminaires, Fig. 3 Refraction and, for $\theta > \theta_{\text{crit}}$, total internal reflection (TIR)

air can also be used to shape the light distribution. Total internal reflection may occur if light travels from a medium with a higher optical density to a medium with a lower optical density, i.e., from high to low refraction index. Glass and plastics have higher refraction index values than air. This means that at the boundary between the medium and air, refraction is away from the normal to the boundary layer, as shown in Fig. 3-left. The middle picture of Fig. 3 shows the situation where the light incidence angle is such that the refraction angle is 90° and thus parallel to the boundary surface. That incidence angle, corresponding to 90° refraction, is called the critical angle. It varies, depending on the type of plastic or glass, between approximately 30° and 40° . If the light incidence is larger than this critical angle, light cannot leave the medium and is reflected with a very high reflection percentage (nearly 100%) as shown in Fig. 3-right.

Total internal reflection with its extremely high reflectance is often used in combination with LEDs to produce efficient and precisely controlled beams in downlight and small floodlight type of luminaires. Often these TIR optics are combined with a collimator lens. Figure 4 shows an example of such a “hybrid” TIR-lens system.

The TIR part controls the largest part of the light radiated from the LED chip, while the integrated collimator lens, located in the center of the system, controls the light radiated from the chip into the central directions. An additional advantage of these TIR-lens systems is that it protects the LED, as it is entirely covered by the bulk optics. For high luminous flux LEDs, bulk plastic optics cannot be used, because of temperature reasons and only glass optics are used. Glass is often also used for lower flux LEDs.

Luminaires, Fig. 4 Example of a rotation-symmetrical TIR-lens solid body for a LED. Blue rays are the result of TIR and red rays the result of the integrated collimator lens (indicated with a lighter tint)

Refractors

Refractors are used to create the desired luminaire light distribution by passing the light from the source through a refractor (Fig. 5). The angle through which the light is bent is dependent on both the shape of the refractive material and its refractive index (Snell's law).

$$\frac{\sin(\alpha_i)}{\sin(\alpha_r)} = \frac{n_{\text{air}}}{n_{\text{material}}}$$

Refracting devices are either lenses or prisms. The type of refractor most commonly employed in indoor lighting is the lens found in tubular fluorescent-lamp luminaires intended for general lighting. It consists of a horizontal plastic panel which is mounted just below the lamp. The panel is flat on the top and has a special pyramidal (prism) or lens structure on the underside, which directs the light in certain directions and reduces the brightness under specific angles. Where in the past prismatic controllers were used, we see today more advanced lens-type refractors that give more

Luminaires, Fig. 5 Bending of light by refraction from the incident angle to the refraction angle

accurate possibilities to shape the light distribution. These types of refractors are also used to produce LED luminaires for general indoor lighting and for road lighting (Fig. 6). Refracting glass bowls were in the past sometimes used for high-pressure mercury and sodium road-lighting luminaires. They have become obsolete because they are heavy, but more so because lighting control in the upward direction, and therefore control of light pollution, is not easily attainable.

Diffusers

Translucent diffusers enlarge the apparent size of the light source. They scatter the light of the lamp in all directions without defining its light distribution. They serve mainly to reduce the brightness of the luminaire and thus the glare created by it. Diffusers are made of opal glass or translucent plastic, commonly acrylic or polycarbonate. The material should be such that it scatters the light while producing the minimum amount of absorption.

Screenings

Screening the Lamp from Direct View

Screening is employed to hide the bright lamp or lamps from direct view. The higher the brightness (luminance) of the lamp, the stricter the requirements for the shielding.

Luminaires, Fig. 6 Micro-lens type of refractor for a LED luminaire for general indoor lighting

The luminaire reflector housing itself, or a built-in baffle, can provide the screening function (Fig. 7). When the sole purpose of the louvre is to shield the lamp from view, diffuse-reflecting material is used, such as a white-plastic louvre or, in the case of floodlights, matt-black metal rings (Fig. 8).

Shielding devices are often combined with the function of defining the light distribution, in which case highly reflective material is used for the louvre.

Color Filters

In certain lighting applications, in particular, display lighting and decorative floodlighting, color is sometimes used to help achieve the desired aesthetic effect. In the past, color filters attached to luminaires containing white light sources were extensively used for this purpose. Both absorption and dichroic (interference) filters were used, although absorption filters in particular (Fig. 9) lower the efficacy of the total lighting system. Typical transmittance values are as follows: for blue absorption filters 5%, for green absorption filters 15%, and for red absorption filters 20%. The consequence of the light absorption is that these filters become warm, which with high-power floodlights may damage the filter. The

Luminaires, Fig. 7 Lamp shielding by the reflector itself (*left*) and by an internal baffle (*right*)

Luminaires, Fig. 8 Simple louvre (*left*) to shield the lamp in a fluorescent-lamp luminaire and (*right*) a floodlight louvre

Luminaires, Fig. 9 Absorption-type color filters

solution where such floodlights are employed is to use dichroic filters, which are a more expensive alternative. Today, colored LED light sources are typically employed where colored lighting is

required. Here the color comes directly from the lamp itself, so the efficacy of the lighting system is much higher.

Light-Distribution Characteristics

The light distribution of a luminaire defines how the luminous flux radiated by the luminaire is distributed in the various directions within the space around it. It is the result of the optical devices used in the luminaire as described above. This is also called luminous intensity distribution, since it is specified in terms of luminous intensities in all the directions in which the luminaire radiates its light (Fig. 10). The luminous intensity diagram is, in fact, the light fingerprint of a luminaire, in digital form (I-table), and is the basis of all lighting calculations.

Basic photometric data that can be calculated from the light distribution are the beam spread and the luminaire light-output ratio. For all types of luminaires and for all types of application, these data provide an insight into the photometric quality of the luminaire.

Luminaires, Fig. 10 The light distribution of a luminaire given by its luminous intensity diagram. The arrows represent the luminous intensities in the directions specified. Here the light distribution is given for all planes, although it is usually only given for one (e.g., the *blue curve*) or two, mutually perpendicular, planes

Mechanical Characteristics

The mechanical function of the luminaire housing is threefold: it accommodates the various component parts of the luminaire, such as the optical system and the various components of the electrical system; protects these against external influences; and provides the means of mounting the luminaire in the installation.

Material

Sheet Steel

Sheet steel is generally chosen for the manufacture of tubular fluorescent luminaire housings for use indoors. The pre-painted sheet steel from the roll is white with diffuse reflection properties. Thus, after having been shaped in the luminaire factory into the desired luminaire form, no finishing-off operations are required.

Stainless Steel

Stainless steel is widely used for many of the small luminaire components, such as clips, hinges, mounting brackets, nuts, and bolts, that have to remain corrosion-free.

Aluminum Alloys

Aluminum alloys, in which other elements have been added to the pure aluminum to improve their mechanical, physical, and chemical protective properties, are used to manufacture cast, extruded, and sheet-metal luminaires. Cast aluminum refers to the process in which molten aluminum alloy is poured (cast) in a mold. Extrusion is the process in which softened aluminum alloy is pressed through the openings of a die. Cast and extruded aluminum alloys are much used in housings for floodlighting and road- and tunnel-lighting luminaires because they can be employed in humid and damp atmospheres without having to add protective finishes. Sheet aluminum is chiefly employed in luminaires for reflectors (Fig. 11). The reflectors are anodized to improve their reflection properties and to protect them from becoming matt.

Plastics

Plastics are used for complete luminaire housings, for transparent or translucent luminaire covers, and for many smaller component parts. All-plastic houses can of course only be employed for light

Luminaires, Fig. 11 Mirror reflector of sheet aluminum protected by a plastic film, which must be removed before use

sources that have a relatively low operating temperature.

Plastic covers are of methacrylate or polycarbonate. Methacrylate maintains its high light transmission properties over a long period, but its impact resistance is relatively low. The impact resistance of polycarbonates is very high and thus offers a high degree of protection against vandalism. It can be chemically treated to protect it from yellowing under the influence of ultraviolet radiation.

Glass

Although glass is heavy, glass covers are used where these have to be positioned close to a light source having a high operating temperature. This is the case, for example, with HID flat-cover road-lighting luminaires and with most floodlighting luminaires. Two sorts of glass are used:

- Regular glass, where no special demands are placed on heat resistance.
- Hard glass, where heat resistance, chemical stability, and resistance to shock are important. Should hard glass break, it will disintegrate into small pieces.

Luminaires made entirely out of glass are extremely heavy and nowadays are seldom employed.

Ceramics

Ceramic material is used in compact housings that are exposed to very high temperatures such as very compact halogen lamp luminaires.

Strength

All luminaires should have housings of sufficient rigidity to withstand normal handling, installation, and use. With indoor-lighting luminaires for fluorescent lamps, stiffness and rigidity of construction are particularly important, since these lamps are relatively large and awkward to handle. Perhaps the most critical part of a luminaire as far as strength is concerned are the mounting brackets. The strength required here is covered by a safety factor: the mounting bracket(s) must be able to support at least five times the weight of the luminaire itself. With road-lighting and outdoor floodlighting luminaires, the mounting brackets must also be strong enough to withstand the highest conceivable wind loading for the location. Here a good aerodynamic shape for the luminaire (characterized by its so-called shape factor) can be advantageous, as it also serves to reduce the strength required for the lighting mast.

Under some circumstances, the impact resistance of the luminaire itself is also important, particularly where protection against vandalism is called for.

Resistance to Pollution and Humidity

The atmosphere can contain many potentially corrosive gases which, in the presence of moisture vapor, will form highly corrosive compounds. In all areas where this danger exists (notably in outdoor applications, indoor swimming pools, and certain industrial premises), luminaires made from corrosion-resistant materials or having protective finishes should be used. In such areas, the luminaire should protect the optical and electrical

components it houses. It should, of course, be fully enclosed. The degree of protection provided by the luminaire is classified according to the International Protection Code (IP Code) as described in an IEC standard [2]. The IP Code consists of two numerals: IP • •.

- The first numeral classifies the degree of protection against the ingress of solid foreign bodies (ranging from fingers and tools to fine dust) and protection against access to hazardous parts.
- The second numeral classifies the degree of protection against the ingress of moisture.

The higher the IP values, the better the protection and thus, the lower the dirt accumulation and the lumen depreciation.

Ease of Installation and Maintenance

Many luminaires are of such a shape, size, and weight as to make mounting them a difficult and time-consuming operation. Mounting but also relamping and cleaning must usually be carried out high above ground level. So the ergonomic design of the luminaire should be such as to make these operations as easy and as safe as possible to perform. For example, covers should be hinged so

that the electrician has his hands free to work on the lamp and gear. A good, ergonomically designed luminaire is one that can be mounted in stages: first the empty housing or a simple mounting plate, which is light and easily handled, and then the remaining parts.

Electrical Characteristics

The electrical function of a luminaire is to provide the correct voltage and current for the proper functioning of the lamp in such a way as to ensure the electrical safety of the luminaire.

Lamp Holders

The most usual types of holders are the Edison screw, the bayonet, and the pin (Fig. 12). Most Edison screw and bayonet holders are made of plastics or porcelain, with metal parts for carrying the current. Porcelain is resistant to high temperatures and has a high voltage-breakdown resistance, which is important considering the high ignition voltage of HID lamps. The pin lamp holders for tubular fluorescent and compact fluorescent lamps are nearly always made of plastic. The metal contacts are spring-loaded to ensure constant contact pressure.

Luminaires, Fig. 12 A variety of lamp holders made of both plastics and porcelain

Electrical Wiring

The electrical wiring in a luminaire must be such as to ensure electrical safety. This necessitates great care in the choice of wire used and its installation. There are a great many different types of wire available, in both single-core (solid) and multicore (stranded) versions, all with various cross-sectional areas and clad with various thicknesses and qualities of insulation. The cross-sectional area (thickness) of the wire must be matched to the strength of the current flowing through it. The insulation of the wire used must be resistant to the high air temperature in the luminaire and the temperatures of the luminaire materials with which it is in direct contact. This is true not only under normal conditions of operation but also in the presence of a fault condition.

Mains Connection

The method used to connect a luminaire to the power supply must be both quick and safe. The practice generally adopted is to incorporate a connection block in the housing, although prewired luminaires in which the electrical connection to the mains is automatically made when the unit is placed in position are also available.

Electrical Safety Classification

The electrical safety classification drawn up by the IEC embraces four luminaire classes [2]:

- Class 0: Applicable to ordinary luminaires only. These are luminaires having functional insulation, but not double or reinforced insulation throughout and with no provision for earthing.
- Class I: Luminaires in this class, besides being electrically insulated, are also provided with an earthing point connecting all those exposed metal parts that could become live in the presence of a fault condition.
- Class II: This class embraces luminaires that are so designed and constructed that exposed metal parts cannot become live. This can be achieved by means of either reinforced or double insulation. They have no provision for earthing.
- Class III: Luminaires in this class are those designed for connection to extra-low-voltage circuits (referred to as safety extra-low voltage, SELV). They have no provision for earthing.

Thermal Characteristics

Temperature Control

A considerable amount of the electrical energy supplied to the lamp is converted into heat. The ballast adds to this heating effect within the luminaire. With very high-powered lamps, the ballast should be placed outside the luminaire in a special ballast box.

For a given lamp/ballast combination, the working temperature reached by the luminaire is dependent upon three factors:

- The volume of the luminaire. The greater the volume, the lower will be the temperature rise inside the luminaire.
- The ease with which the heat generated within the luminaire can be conducted through it to the surrounding air. One way of promoting airflow through the housing is to make use of heat-conducting materials in its construction. Most metals are suitable in this respect, while plastics, on the other hand, are thermal insulators and cannot, therefore, be employed as housing materials where high-power lamps are involved.
- The cooling effect of the surrounding air. Good heat dissipation calls for large surface areas to be in contact with the surrounding air. Luminaires for high-power lamps, such as high-bay luminaires, floodlights, and some LED luminaires that are very sensitive to high temperatures, are therefore provided with cooling fins (Fig. 13). Some types of industrial luminaires are provided with air vents in the top of the housing to allow the warm air to escape.

Luminaires, Fig. 13 Metal halide high-bay luminaire (*left*) and recessed LED downlight with cooling fins

Protection Against Flammability

The flammability of a luminaire operating under fault conditions is an issue with luminaires made of plastics. But the combustion behavior of such luminaires is not just material dependent; it also depends on the shape and thickness of the luminaire housing.

Aesthetics

No less important than the functional characteristics of a luminaire is what is termed its aesthetical appeal, that is to say, its appearance and styling. In interiors, all non-recessed luminaires are clearly visible, and so whether switched on or not, their design should be in harmony with that of the interior. In outdoor lighting, it is usually only the daytime appearance of the luminaires, when these are clearly visible, that is important: particularly in built-up areas, their design can make a positive contribution to the attractiveness of the locality.

Approval

Luminaires always have to comply with the appropriate safety rules. UL (Underwriters Laboratories) is the US mark for demonstrating compliance with all US safety standards, and ENEC (European Norms Electrical Certification) is the similar European mark (Fig. 14).

Luminaires, Fig. 14 UL and ENEC certification marks. The number in the ENEC mark indicates the country of the institute that has given the European approval

[Luminance measurement device](#)

Definition

A luminance meter is a device used to measure the photometric unit, luminance, in a particular direction at a solid angle from a surface. There are three methods to measure luminance. The first method is the conventional luminance meter that uses a designed sensor with a spectral response that closely matches the $V(\lambda)$ spectral luminous efficiency function of the human eye. The second method is the measured luminance that is derived through the illuminance measurement and subsequent calculations. The third method is the imaging luminance measurement device that measures the luminance in a single direction and is similar to a digital camera which records color images.

Introduction

The luminance of a light source (integrating sphere with known output aperture) is determined from the measurement geometry and illuminance measured by a photometer. The luminance of the light source is obtained as Eq. (1),

$$L_v = \frac{E_v D^2}{A} \quad (1)$$

where E_v is the illuminance at a distance D between the aperture plane of the source and the photometer and A is the area of the source aperture. The distance D depends on the radius of the limiting aperture r_1 , the radius of the source r_2 , and the physical distance d between the source and the aperture according to Eq. (2):

$$D^2 = r_1^2 + r_2^2 + d^2 \quad (2)$$

Equation (2) is accurate within $\pm 0.01\%$ for distances that are more than one decade greater than the radius [1].

Since a regular digital camera does not equip the photopic filter, its pixels are specified in a device-independent RGB color space in general. The photometric data can be calibrated from a color image through a series of calculations that involve conversion from RGB to CIE's absolute

color space pixel-by-pixel. In addition, the human vision system can adapt to luminance in a very wide range (10^{-6} – 10^6 cd/m²), but the digital image's dynamic range is 8 bit or less than 12 bit. Therefore, in order to measure a high dynamic scene, it is necessary to know the exposure values of the digital camera as Eq. (3):

$$EV = \log_2 \left(\frac{f^2}{t} \cdot \frac{S}{100} \right) \quad (3)$$

where f is aperture, t is shutter speed, and S is ISO sensitivity value. The dynamic range is just adjusted by shutter speed if both the aperture and the ISO value are fixed during the measurement. The processes of calibration for the imaging luminance measurement device are the procedure for determining the mathematical transform between luminance and the digital data L of image with shutter speed t [2].

Applications

An imaging luminance measurement device (ILMD) is capable of measuring illuminance in an image. It can automatically quantify the distribution or the uniformity of light. This is much more powerful than the conventional single-point luminance meter. For example, an ILMD is utilized for measuring the luminance of all pixels of flat panel displays [2]. Figure 1 depicts the measurement of the luminance of vertical or horizontal test patterns shown on a TFT-LCD display with an ILMD in a slightly tilted position [2]. The subsequent image processing includes calculating the spatial frequency response (SFR) of the image using a slanted-edge algorithm, obtaining resolution at a specified decrease (e.g., 50%) in the SFR of the device under test (DUT), and finally, specifying the resolution of the DUT in terms of the image sharpness.

In addition, an automatic measurement system based on an ILMD also measures the photometric properties of road and tunnel lighting systems [3, 4]. Figure 2 depicts an automatic system for this purpose. Compared with a single-point luminance

Luminance Meter,

Fig. 1 Sharpness measurement of FPD by using a ILMD

Luminance Meter, Fig. 2 Automatic measurement and analysis program for road and tunnel lighting systems

meter (conventional luminance meter), the ILMD is more precise and time-saving for measuring road and tunnel lighting.

Since the rapid growth of light-emitting diode (LED) technologies, the adjustable lighting on billboards using LED has become increasingly popular. Many of these products are pushed to much higher contrast in spatial and/or temporal configurations to attract attention. However, the glare and/or flicker of the LED sources may produce an uncomfortable visual experience.

Therefore, Hsu et al. [3] proposed a measurement system for regulating between flicker and glare by using perceptual ratings of LED billboards under various conditions. Authors performed both objective and subjective evaluations of flashing LED billboards in interior spaces. The objective flicker and glare evaluations were carried out by taking temporal and spatial measurements, respectively. The properties of the flicker and glare values obtained are reproduced under physical conditions. The visual results were modelled

by simple equations as a function of objective measurements in terms of a low-pass flicker index and unified glare rating. Thus, an effective method was developed for regulating the degree of flashing LED lighting using an ILMD.

[Cold body radiation](#); [Cold light](#)

Definition

Luminescence is the emission of optical radiation caused by a non-thermal process [1]. Luminescence is therefore a form of “cold body radiation” or “cold light,” since it does not result from heating (i.e., from a relatively cool material, not above room temperature). It is therefore distinguished from light emitted by *incandescence*,

which is a form of blackbody radiation from a heated material, that is, “hot light” whose spectral power distribution is determined by its thermal temperature.

The term *luminescence* is also often used to generally discuss *fluorescence* and *phosphorescence* phenomena. However, this is only one type of luminescence, known as *photoluminescence*, caused by the absorption of optical radiation, and there are many other types of luminescence (e.g., cathodoluminescence, electroluminescence, chemiluminescence, bioluminescence, triboluminescence, thermoluminescence, etc.) classified by their different modes of activation, which are described below.

Overview

There are many early reported observations of the phenomenon of “luminescence.” For example, it was reported in the early seventeenth century by an Italian cobbler, Vincenzo Cascariolo, when he was searching for the philosopher’s stone by heating a mixture of coal and stones containing barium sulfate and found that, after cooling, it emitted a bluish glow in the dark for several hours [2]. The term “*phosphorescence*,” named for the luminous glow over the element phosphorus, is now frequently used for this phenomenon of long-lived or delayed luminescence. However, the term “luminescence” was first introduced as “*luminescenz*” in 1888 by the German physicist, Eilhard Wiedemann when he coined this term to describe the general phenomenon of light that did not depend upon the temperature of the substance concerned [3]. The term comes from the Latin root “*lumen*” meaning “light” plus “-escence.”

The process of luminescence occurs when an atom, molecule, crystal, or polymer is non-thermally excited to an excited electronic or vibrational state. When this excited specimen drops back down to its equilibrium state, it emits radiation if it is not in thermal equilibrium with its environment. The emitted radiation is usually in the visible spectral region but it can also be in the ultraviolet or infrared spectral regions and is generally of lower energy, that is, *downconverted* (longer wavelength) compared to the excited

radiation. This excitation of luminescence can be caused by a wide variety of mechanisms, with many technologically important applications, which are described below.

Types of Luminescence and Their Applications

The main categories of specialized luminescence and their mode of activation energy are [2, 4]:

Electroluminescence (EL) – action of an electric field in a gas or in a solid material

Cathodoluminescence (CL) – caused by the impact of an incident electron beam on certain types of luminescent materials, such as the coating of a television screen

Photoluminescence (PL) – caused by absorption of optical radiation

Radioluminescence (RL) – caused by X-rays or radioactive radiation

Chemiluminescence (ChL) – caused by energy released by a chemical reaction, usually oxidation

Bioluminescence (BL) – caused by chemiluminescence occurring in living organisms

Triboluminescence or mechanoluminescence (ML) – caused by the action of mechanical forces

Thermoluminescence (TL) – occurs when a previously excited luminescent material is heated

This is not an exhaustive list but illustrates the wide variety of luminescent mechanisms. Of these different types of specialized luminescence, *electroluminescence* is perhaps the most technologically important since a light emitter has to be able to produce light in an efficient manner under electrical excitation [5]. The passage of electric current through a gas can produce light as in gas lasers, sparks, arcs, lighting, coronas, and electrical-discharge lamps such as deuterium and xenon. Light production by direct electroluminescence occurs when a beam of electrons is accelerated and impinges on a phosphor screen. This is known as *cathodoluminescence*, and the best-known example is the technology used in a cathode ray tube

(CRT) color television screen, where three electron beams striking an array of red, green, and blue-emitting crystal phosphors, can lead to a full range of colors. The cathodoluminescence technique induces the emission of light of characteristic wavelengths in a wide spectral range. This is utilized in the scanning electron microscope (SEM)-CL to obtain chemical composition information and spatial details of semiconducting materials and for detecting trace rare-earth elements [5].

Luminescence from phosphors, which are based on wide band-gap materials containing activators, which cover the entire visible range, is used in a number of materials and devices, including fluorescent lamps and tubes, displays, and light-emitting diodes (LEDs) [6]. LEDs, which are solid-state semiconductor devices, have a “tunable color” whose emission wavelength range depends upon the properties of the doping impurities that are used to form the electrical junction. For this reason, photoluminescence is commonly used for the analysis of the optical behavior of impurities in semiconducting materials for their use in optoelectronic devices [5]. In 1966, a phosphor coating was applied to a blue LED to create the world’s first white LED. In the past 20 years, this technology has shown a phenomenal rate of improvement in efficiency, rapidly replacing traditional incandescent and fluorescent lamps for general lighting applications.

For photoluminescence-based lighting to be efficient, the number of photons (light) that is emitted per photons absorbed by the material (*photoluminescence quantum yield*) needs to be high. Electroluminescent quantum dot (QD) displays, which are a self-emissive technology that does not depend on inefficient down-conversion of blue photons to red and green photons but electrically stimulates the QDs to emit photons, promise dramatic improvements in efficiency over photoluminescent QD displays because there is no wasted light [7]. As mentioned above, photoluminescence can be further subdivided into two forms: *fluorescence* and *phosphorescence*. *Fluorescence* is due to transitions between states of the same multiplicity (i.e., allowed transitions) and the emitted radiation generally appears within 10 nanoseconds of

excitation. *Phosphorescence*, on the other hand, is due to transitions between states of different multiplicity (i.e., forbidden transitions) and the emission of optical radiation appears 10 nanoseconds or longer after the excitation. However, for most types of optical radiation detectors used in photoluminescence spectroscopy, for example, photomultipliers and silicon photodiodes, the time constant of the detector is too long in order to be able to distinguish between these two forms of photoluminescence, and the term fluorescence is commonly used for the measurement of both phenomena.

Radioluminescence, also known as *scintillation*, is induced by the various “rays” emitted by ionizing radiation interacting with radioactive substances. This includes alpha rays (helium nuclei), beta rays (electrons), and gamma rays (high-energy electromagnetic radiation). A remarkable natural occurrence of radioluminescence is the aurora borealis, in which radioactive processes in the sun, excited by the solar wind, produce large numbers of electrons and ions that emit into space. Self-luminous paints that are used in dial markings on watches and other instruments are made of a radioactive substance, for example, tritium or radium, hitting a crystal phosphor, and producing tiny “*scintillations*” that are visible to the human eye.

Chemiluminescence is produced by chemical reactions, mainly oxidation, at low temperatures. Commercial forms of chemiluminescence include emergency glowsticks and glowing liquid-filled plastic tubes.

Bioluminescence is light produced from a chemical reaction involving a chemical substance in a living organism and is a form of the more general chemiluminescence. It occurs in glow-worms, fireflies, fungi, putrefied meat, and in many oceans or sea creatures, such as jellyfish and deep-sea water fishes.

Triboluminescence is the production of light by mechanical disturbances on certain crystalline substances. This can include friction and static forces such as crushing, grinding, cutting, etc. For example, the crushing of sugar crystals or the cutting of ruby or sapphire crystals with a diamond saw can produce light.

Thermoluminescence and optically stimulated luminescence (OSL) are used in luminescence-based dating, for example, on the planet Mars for dating sediments and in fluvial deposits in order to determine the age of sediments deposited during the last glacial-interglacial cycle. These techniques are also used in nuclear-accident dosimetry and in the investigation of luminescent processes [8].

Luminescent Materials

Luminescent materials can be classified into several broad groups. These are summarized in Table 1, along with some specific examples and typical applications [4].

Fluorescent whitening agents (FWAs) or optical brightening agents (OBAs) are an important class of organic luminescent materials. These are

Luminescence, Table 1 Examples of luminescent materials and their applications

Classification	Examples	Applications
Aromatic molecules	Xanthenes, aminocoumarins, stilbenes, and oxazines	Scintillators, luminescent dyes/paints, FWAs, and dye lasers
Inorganic crystals	Diamond, ruby, and alkali halides	Scintillators, solid-state lasers, and jewelry
Noble gases	He, Ne, Ar, Kr, and Xe	Discharge lamps, gas lasers, and scintillators
Inorganic ions	Rare earths	Nd glass lasers and glass scintillators
Simple inorganic molecules	N ₂ , I ₂ , and CO ₂ H ₂ , D ₂ , N ₂ , and Hg	Gas lasers Discharge lamps
Biological molecules	Amino acids, nucleotides, Vitamins, and hormones	Biological research
Aliphatic molecules	Paraffins and cyclohexane	Emit in far-UV

generally sulphonated stilbenes that absorb short-wave radiation in the ultraviolet and violet range (below 430 nm) and emit blue light with a peak wavelength around 450–470 nm, producing a bluish tint, which increases our perception of whiteness significantly, so that the FWA-containing material appears to be “whiter than white.” These FWAs are used in the manufacture of white products such as paper and textiles and are used in laundry detergents, some plastics, and cosmetics.

Photoluminescent inorganic pigments are used in diverse ways, including outdoor displays and in the manufacture of safety goods including outdoor safety signing and marking and safety clothing. These pigments absorb daylight radiation in the UV or short-wave visible and emit at longer wavelengths in the green-yellow or yellow-orange visible range, which enhances their perceived colorfulness and visibility.

Luminescence in inorganic crystals, such as ruby and diamond, is due to the presence of impurity centers or crystal defects. This process can be very efficient and is used in the manufacture of solid-state lasers. The noble gases, such as He, Ne, Ar, Kr, and Xe, are often used in low-pressure discharge lamps, which emit light of different colors and are used in advertising installations. On the other hand, low-pressure discharge lamps made with mercury vapor and phosphor (e.g., fluorescent lamps), are suitable for general lighting purposes. High-pressure discharge lamps are usually made using Hg or other elements combined with Hg and can also produce significant amounts of thermal radiation, that is, not only luminescence. One of their main applications is for the illumination of large indoor or outdoor spaces, such as sports stadiums, and parking lots.

Luminescent solid-state materials have largely displaced gas discharge luminescence in many applications because of the high emission efficiencies demonstrated by both organic light-emitting diodes (OLEDs) and inorganic light-emitting diodes. Other solid-state luminescent materials and devices of current interest include down-conversion materials, nanomaterials and powder, and thin-film electroluminescent phosphor materials and devices. Lanthanide-doped

nanoparticles are an emerging class of luminescent nanomaterials that are of considerable recent interest for both biological sciences (e.g., use as biological labels) and photovoltaic (PV) applications because of their low toxicity, high chemical stability, and upconversion properties, that is, potential to convert light between different spectral regions with high signal-to-noise (S/N) sensitivity [7].

Photoluminescence is the most widely used technique for the analysis of semiconducting materials because it is much more sensitive than reflectance or absorbance measurements for detecting impurities at low concentrations [5]. Because of its high sensitivity, intrinsic selectivity, non-invasive nature, and potential for multiplexing applications, luminescence techniques are one of the most widely used detection methods in biomedical science. Fluorescence spectroscopy is also an important tool in biological research involving structure elucidation and the study of interactions in proteins and nucleic acids [9].

MacAdam, David L

Michael H. Brill¹ and Rolf G. Kuehni²

¹Datacolor, Lawrenceville, NJ, USA

²Charlotte, NC, USA

David Lewis MacAdam (1910–1998) was an American physicist and color scientist who made important contributions to colorimetry, color discrimination, color photography and television, and color order.

MacAdam grew up in Philadelphia, attended Lehigh University, and in 1936 received a PhD in physics from MIT. Under Prof. Arthur C. Hardy, he originated the first course in color measurement and assisted Hardy in the preparation of *Handbook of Colorimetry*, published in 1936.

Upon graduation, MacAdam joined the Research Laboratories of the Eastman Kodak company in Rochester, NY, from where he retired as a Senior Research Associate in 1975. Subsequently, he was named Adjunct Professor at the University of Rochester, Institute of Optics, where he remained active until 1995. At Eastman Kodak, among many other things, he helped to establish the theoretical basis for color photography, including color masking as compensation for unwanted dye layer absorptions [1].

Optimal Object Color Limits

While still studying, MacAdam published in 1935 two papers in which he offered a geometric proof of the optimal-color theorem and calculated the optimal object color solid raised over the CIE chromaticity diagram, using the newly established CIE standard observer and illuminant C and A data from 1932 [2, 3].

MacAdam Ellipses

One of MacAdam's best-known contributions was in support of technological color control. Assuming that the basis of color difference perception was the statistical error in matching the appearance of a given color stimulus, he conducted an extensive experiment with one observer, the result of which was expressed in the CIE chromaticity diagram in form of statistically derived ellipses, published in 1942 [4]. However, the resulting Friele–MacAdam–Chickering color difference formula proved less effective in predicting perceived color differences than formulas derived on other bases. In attempting to convert the ellipses to circles of equal size, MacAdam encountered the non-Euclidean nature of psychophysical color space.

Instrumentation and Computation

In the mid-1940s MacAdam pioneered the use of computers in colorimetric computations, established Hardy's reflectance spectrophotometer as a reliable industrial measuring instrument, and invented a tristimulus integrator as an accessory.

Principal-Component Analysis of Daylight

With Deane B. Judd and Günter Wyszecki, MacAdam performed the first principal-component analysis of phases of daylight of various correlated color temperatures, demonstrating that they can be represented as linear combinations of a limited number of spectral components [5].

Optical Society of America Uniform Color Scales

MacAdam was a leading member of the committee of the Optical Society of America that in 1947, at the suggestion of the US National Research

Council, began work on a perceptually uniform colorimetric model of the color solid. Upon the retirement of its first chairman D. B. Judd, MacAdam was elected chair. The result of the committee's work was published in 1974 as "Uniform Color Scales," [6] with OSA publishing a related color atlas with 558 samples in 1977.

MacAdam was a major contributor to OSA's 1953 book *The Science of Color* [7]. His interest in the history resulted in publication in 1970 of *Sources of Color Science* [8], a compilation of 26 seminal papers on color science, from Plato to Le Gros Clark, several translated for the first time into English. In 1981 he published *Color Measurement: Theme and Variations*, a presentation of fields of color science in which he made important contributions [9]. He also authored some 100 peer-reviewed journal articles.

MacAdam was president of the Optical Society of America in 1963 and editor of the *Journal of the Optical Society of America* from 1964 to 1975. He was active in the Inter-Society Color Council and the Commission Internationale de l'Eclairage (CIE). He received honors from many societies, including the Frederic Ives Medal of the Optical Society of America in 1974.

Mach Bands

Rolf G. Kuehni
Color Science Laboratory, Carolina State
University, Raleigh, NC, USA

Definition

Mach bands are brightness illusions, originally referring to a situation where a lighter and a darker sharp-edged gray area are separated from each other by a gray area where the brightness transforms uniformly from the brighter to the darker field. When looking at an image producing perceived Mach bands (Fig. 1), two bands are seen, a lighter one between the light and the intermediate fields and a darker one between the intermediate and the dark fields, even though the physical composition of the three fields does not contain physical sources of the bands. More recently, the term Mach bands is also applied in the case of sharply adjacent gray fields of different reflectance, each band physically uniform, where, in addition to the perceived change in lightness across each band, very narrow lighter and darker bands may be perceived near the line where two fields connect (Fig. 2).

Mach Bands, Fig. 1 Image of classical Mach effect. Section **a** is a light gray field with uniform reflectance; from **b** to **c** there is a uniform reflectance transition from the color of section **a** to section **d** which is a reflectively uniform dark gray field; the light and dark perceptual Mach bands are located at **b** and **c**, respectively

History of Mach Bands

Perceptual band effects were discovered by the Austrian chemist Ernst Mach (1838–1916) in 1865 based on the appearance generated when disks that have different white and black patterns on them are rapidly rotated, an example of which is shown in Fig. 3a. Figure 3b is Mach's representation of the appearance when looking at the rapidly spun disk of Fig. 3a. The inner bright circle is perceptually experienced at the location β in Fig. 3a, and the outer bright circle at location γ . When black and white in Fig. 3a are reversed, the perceptual result of rapid rotation is dark perceptual bands at locations β and γ . Mach reported his findings of the perceptual illusion bands in five articles published between 1865 and 1868, only the first two of which are referenced here ([1, 2] English translations in F. Ratliff, 1965, [3]).

In later experiments, Mach thought of disk designs that produced both light and dark bands from the same spinning disk. He also produced Mach bands in square format images by fastening the related multiple identical images onto a cylinder that he then rapidly rotated.

The size of the distance between β and γ in Fig. 3b, comparable to the distance between **b** and **c** in Fig. 1, is an indicator of the perceptual intensity of the resulting Mach bands. The narrower the reflectance transition sector is (the closer to vertical the line between **b** and **c** in Fig. 1), the more perceptually strong the related Mach bands are. An example of the relationship between physical stimuli and perceptual results is shown in Fig. 4 [4]. The solid black line represents the physical measure of luminance (represented in foot-lambert), proceeding at two points from constant value to transitioning values. The black line with open circles represents average perceived lightness before and after the transition points, indicating the dark Mach band on the left and the light one on the right. With the rising solid line of luminance being relatively steep, the resulting light Mach band is perceived as particularly light. However, as the transition sector approaches or is zero in width the perceived Mach bands become very weak.

Mach Bands, Fig. 2 Five rectangular fields, each of which is physically uniform but changes in perceptual appearance from left to right. For some viewers, very narrow adjacent light and dark Mach bands are visible where fields touch

Mach Bands, Fig. 3 (a) (left) and (b) (right). Both images are from Mach's original article [3]. The left figure is an image of one of the circular disks that Mach rapidly rotated to demonstrate the phenomenon. Figure 3b is Mach's representation of the appearance of the rapidly

rotated disk shown in Fig. 3a. The inner perceived white Mach band appears at location β ; and the middle white band at location γ on the disk. Copyright permission unattainable (publisher no longer exists and author passed away)

The term Mach bands is now also applied when there is no transition field but the lighter and the darker fields are adjacent. In this situation, the perceived bands, a lighter one on the edge of the light field and a darker one on the edge of the dark field were reported in 1861 by the French Chemist M. E. Chevreul (1786–1889), known as the Chevreul illusion [5]. It is experienced when placing homogenous bands of different brightness/lightness adjacent to each other (Fig. 2). Even though the bands are physically uniform they are perceived as not so, with the appearance being lighter where the field is adjacent to a darker

one and vice versa. The effect of the Chevreul illusion has been enlarged in the Craik-O'Brien-Cornsweet illusion [6] by placing a narrow band of increased lightness at the edge of the light field and one of decreased lightness at the adjacent darker band. This physical change enlarges the perceptual effect of the Chevreul illusion. It does not play a role in the definition of Mach bands.

The classical Mach bands have been experimentally investigated since their discovery. In 1972, A. Fiorentini surveyed research pertaining to the Mach band phenomena since the 1950s [7]. This included determining the effect of the

Mach Bands, Fig. 4 A comparison between the physical dimensions of a Mach band stimulus (solid line) and the average perceived perceptual results from a number of observers (line with open circles), indicating the location of the dark (lower bulge) and the light (upper bulge) peaks of the resulting perceived Mach bands [4]. Reprinted with permission from the copyright holder The Optical Society of America (OSA)

steepness of the transition from low to high light levels (examples of such research are found in [8–10]). Substantial inter-observer variability in the perception of the Mach band effect has been discovered by multiple authors over the decades.

Mach bands are related to achromatic fields or to the reflectance differences of chromatic fields with hue and chroma having no apparent effect on their perception. An empirical interpretation of classical Mach bands was offered in 1999 by R.B. Lotto, S. M. Williams, and D. Purves [11]. They believe that Mach bands may be the result of the response of the human visual system to the relative frequency of certain reflectance patterns generated from light reflected from objects with graded surfaces. They offered as an example an image of a metal cube with some rounded edges, illuminated by sunlight (Fig. 5). The relative luminance of the reflected light from points 1 to 4 in the image, to a degree, duplicates that of the classical Mach bands. According to these authors, the human perceptual system is presumed to respond to a relatively high frequency of occurrence of such visual situations in nature. This hypothesis has not found general acceptance by sensory biologists.

An unresolved major issue regarding Mach bands is at what level in the vision process they

are being generated. It was initially presumed that Mach bands are generated in the retina but soon after, more complex processes in the visual system were also proposed. A detailed, scientifically solid, neural model does not yet exist. Early explanation attempts have been reviewed by F. Ratliff in his 1965 book *Mach Bands* (3). An interesting theory based on response normalization was proposed by F. A. A. Kingdom in 2014 which states, "... whereby the gains of early visual channels are adjusted on a local basis to make their responses more equal" [12].

Summary

Mach bands are perceptual illusions created in the brain/mind from neurobiological information generated in the retina when viewing stimuli of adjacent fields of different lightness, either separated by an intermediate field with reflectance changing from that of the lighter field to that of the darker field or by viewing two directly adjacent fields of different reflectance. While best visible in achromatic fields, chromaticness itself does not affect the Mach band effect. The complete neural basis of the perception of Mach bands has so far not been discovered.

Definition

Magno-, parvo-, and koniocellular pathways are the three visual pathways in primates. These pathways are established at the level of the lateral geniculate nucleus (LGN) of the thalamus. They are formed of morphologically distinct cellular layers that receive information from different types of retinal ganglion cells and project to different layers in the primary visual cortex.

Anatomical Considerations

The LGN layers of each of the three visual pathways have a specific cytoarchitectonic structure. The names of the pathways are derived from these structural characteristics [1, 2]. Magnocellular (M) cells have relatively large bodies (lat. *Magnus*: large), parvocellular (P) cells have smaller bodies (lat. *Parvus*: small), while koniocellular (K) cells (gr. *Konios*: dust) are very small.

As can be seen in Fig. 1, structural differences between the three pathways emerge at the level of the retina as each pathway receives projections

from a different group of retinal ganglion cells. The M pathway is based on inputs from diffuse bipolar cells and parasol ganglion cells. Receptive fields of these cells combine inputs from long (L)- and middle-wavelength (M) cones additively (L + M; the achromatic dimension). Although retinal ganglion cells that ultimately project to the P layers are heterogeneous, midwavelength bipolar and midwavelength ganglion cells form the bulk of the P pathway. The receptive fields of P cells which receive inputs from midwavelength ganglion cells oppose inputs from L and M cones (L–M; reddish-greenish dimension). The two intermediate K layers receive projections from small bistratified cells. The receptive fields of such K cells oppose the excitatory input from S cones with the inhibitory input from L and M cones (S–(L + M); bluish-yellowish dimension). K layers also receive inputs from several other cell types which oppose S-cone input to some combination of L and M cone input (+S – ML large bistratified, –S + ML large sparse, and two –S + ML giant sparse ganglion cells), but their role in color vision is still not fully understood [1, 3]. The distinction between the processing of luminance signals

Magno-, Parvo-, and Koniocellular Pathways, Fig. 1 Structure of the lateral geniculate nucleus, including a map of retinal inputs and cortical outputs. There are six thick layers, with M cells found in the lowest two and P cells found in the top four of these layers. K cells form six thin layers. The first K layer is positioned ventral to the first M layer, while the others are intermediate to the six LGN layers. The M cell axons terminate primarily in layer 4Cα of the primary visual cortex (V1) while the P cell axons

terminate primarily in layers 4Cβ and 4A of V1. The six K layers are further subdivided on the basis of their projections. The two dorsal K layers project into layer 1 of the primary visual cortex. The two intermediate K layers receive information from small bistratified retinal ganglion cells as well as several other types of cells with S-cone input and project it into layers 3 and 4A of the V1. The two ventral K layers project into the superior colliculus

(L + M) and the processing of two types of chromatic signals (L–M and S-(L + M)) by geniculate cells had led to their conceptualization as the three orthogonal visual mechanisms. Such a conceptualization is implemented in the DKL space, a physiological color space based on the seminal study of macaque LGN cell response properties conducted by Derrington, Krauskopf, and Lennie [4].

Historical Overview

Based on his observations of three different types of axons in the rabbit optic nerve, Bishop speculated in 1933 that visual information is likely to be processed along morphologically distinct pathways that operate in parallel [5]. An in-depth historical overview of research into parallel visual pathways is provided by Casagrande and Xu [6]. In brief, by the end of the 1980s, pathway-tracing studies on primates confirmed Bishop's speculation, establishing that different retinal ganglion cell classes projected to separate layers in the LGN, which subsequently projected to separate cortical layers. Numerous physiological studies uncovered marked differences in spatial, temporal, and contrast sensitivities between various cell types that were found in the retina, LGN, and the primary visual cortex. Early studies of primate LGN cell properties attempted to relate their findings to extensive research performed on cats' retinal ganglion cells (X, Y, and W types) since the 1950s. Attempts were also made to relate the newly found geniculate visual pathways to the ventral or "*what*" cortical stream, which was proposed to subserve the processing of objects' visual attributes, and the dorsal or "*where*" cortical stream, which was proposed to subserve the processing of objects' locations [7]. In 1988, Livingstone and Wiesel proposed an integrative model of retinogeniculocortical pathways [8], linking the M pathway to the processing of motion due to the transient responses and high achromatic sensitivity of its neurons and the P pathway to the processing of form and color due to its neurons' sustained response to chromatic contrast and weak response to achromatic contrast.

Livingstone and Hubel's model epitomized the modular approach that was prominent at the time, relating discrete brain structures to specific cognitive or perceptual functions. The koniocellular (K) pathway was ignored by Livingstone and Hubel's model. At that time, the K layers in primates were considered to be too thin to contribute substantially to any single cortical module. Between the 1950s and 1970s, the K pathway was generally studied in bush babies and lorises, which are nocturnal prosimian primates [2]. Subsequent studies confirmed that K cells in these species were quite similar to those in other primates. Since then, a range of studies was performed on the primate K pathway, revealing diverse functional properties of K cells, including their role in color vision. At the same time, much more has become known of retinal processing, with 20 different types of retinal ganglion cells identified [9]. Cortical projections of M, P, and K cells have also been mapped more extensively, as will be discussed in the next section.

Functional Considerations

Numerous neuroanatomical and neurophysiological studies have investigated the properties of the three parallel pathways. As noted in the historical overview, continuous attempts have been made to relate the pathways to the processing of different visual properties: motion processing, form processing, luminance and color processing, and so on. As evidence accumulated it became more and more clear that simple and direct associations between physiological responses and perceptual properties are difficult to establish [1, 10, 11]. In fact, M, P, and K pathways can only tentatively be treated as wholly separable when it comes to their function: for example, the M pathway contains cells that project information into dorsal cortical areas subserving motion processing, which fits Livingstone and Hubel's model, but it also contains cells that project information into ventral areas subserving object representation [6].

The most robust and the least disputed evidence for differential processing between M, P,

and K pathways comes from primate color vision research. Strong links have been established between the M pathway and the luminance (L + M) channel. The chromatic L–M channel, which computes the difference between L and M cone signals providing a reddish-greenish dimension of color, maps on to the cells of the P pathway. Furthermore, the L–M cone-opponent mechanism provides signals that could be transmitted in combination with luminance information [4]. The view that such “multiplexing” through the L–M channel underlies achromatic vision is based on the fact that P cells are much more numerous than M cells and was initially strengthened by observations of poor spatial acuity of M cells, although recent data showed much smaller differences in M and P cell receptive field center sizes than originally found. In fact, there is an opposing view that strict subcortical segregation of luminance and L–M signals would be beneficial, since it would optimize signal transmission in a noisy, bandwidth-limited system such as primate vision [1].

Unlike P cells, K cells that receive S-cone input from small bistratified cells are not considered to make a significant contribution to luminance processing. Their receptive fields are larger than those of luminance-sensitive cells [12], compromising their usefulness for high-acuity spatial vision. Their signal is amplified cortically, being weakly present in many cells from V1 onward [13]. S-cone-sensitive K cells may still contribute to functions other than just color appearance. For example, they project directly to motion-sensitive cortical area (MT/V5) [10].

While it is not possible to fully equate geniculate pathways with psychophysically identified luminance and chromatic channels, a certain degree of functional overlap between them is evident and has been used in many studies that rely on luminance or chromatic contrast to attempt to isolate or bias visual processing toward different pathways. As M pathway dysfunctions have been hypothesized to underlie schizophrenia, autism spectrum disorders, dyscalculia, and dyslexia, the ability to isolate this pathway through carefully designed stimuli is of keen interest to clinical neuroscience. Studies in this field do not only

compare responses to luminance stimuli with those to isoluminant stimuli but also often rely on other well-known processing differences between parallel visual pathways. Fast temporal frequency, low luminance contrast, and low spatial frequency are generally thought to bias processing toward the M pathway, while low temporal frequency, high chromatic contrast, and high spatial frequency are assumed to bias processing toward the P pathway. It is paramount to be careful when interpreting the findings of such studies. For example, besides many transient response neurons, the M pathway also contains some neurons with sustained responses. Similarly, while contrast sensitivity functions for luminance and chromatic stimuli do indeed differ, many spatial frequencies that lead to larger excitation in one pathway happen to concurrently cause some excitation in the other pathway. Therefore, the level of bias to one or the other pathway is very difficult to quantify. Finally, responsiveness of M, P, and K pathways to various visual features cannot be assumed to translate directly into perceptual sensitivity for these features. For example, P cells with receptive fields in the parafovea are sensitive to a wide range of temporal frequencies, but human observer performance reveals that the sensitivity of the visual system as a whole does not match the sensitivity that is present in this geniculate circuitry [14]. Thus, some of the sensitivity evident in P cells is not utilized at subsequent stages of processing that drive behavior.

Isolating subcortical processing streams or biasing processing toward a certain pathway is ultimately complicated by the fact that the separation of signals from different visual pathways is not maintained in the cortex. Receptive fields in V1 are larger than in the LGN, indicating that each V1 cell receives input from several LGN cells. S-cone signals become more prominent in the cortex, with weak S-cone signals being found in many V1 neurons. Finally, LGN cells with chromatic sensitivity show preferential responses to stimuli that align with the S-(L + M) and L–M mechanisms, but V1 cells have much more widely distributed color preferences. This indicates that S-(L + M), L–M, and L + M signals start interacting in the cortex. In fact, most of the

early visual cortex contains neurons that are tuned to both color and luminance while also being sensitive to certain spatial properties, e.g., orientation [13].

Summary

Magno-, parvo-, and koniocellular pathways are established at the level of the LGN. They receive inputs from different retinal ganglion cells and project to different layers of the V1, leading to parallel processing of visual information. Parallel visual pathways have been extensively researched both in terms of their structure and in terms of their functional properties. Geniculate pathways are of interest for color scientists as the retinal projections they receive differ in chromoluminance content: while the M pathway is solely devoted to the processing of luminance information, the P and K pathways also subserve chromatic processing. Other differences between pathways concern contrast sensitivity and spatial and temporal processing, with the M pathway being preferentially responsive to high temporal but low spatial frequencies and to low luminance contrast. Despite these recognized differences, studies that attempted to relate these pathways to specific visual functions have met with limited success. Such research is complicated by the fact that data on physiological responses of M, P, and K cells does not always correspond to behavioral data obtained from human observers under the same conditions [14]. This is at least partly caused by the fact that visual signals undergo much further processing in the cortex, as signals from different pathways get recombined from primary visual cortex onward [11]. There is growing evidence that contributions of M, P, and K pathways to various perceptual functions are not as segregated as was once thought. Recent research has also revealed that subcortically there are likely to be more than just three parallel visual pathways, based on the evidence that the processing in the retina itself is already very complex and driven by a wide array of cells with different inputs and connectivity [15].

Definition

Materials – integrating hue, brightness, intensity, hardness, and occasionally form, into a single category, e.g., jade (axes), gold (beads) – were decisive for the development of increasingly abstract linguistic color categories from the era of the earliest documented language sources.

Material Color

Extremely controversial is the linguistic importance of materiality, with colors of materials used in personal adornment and ornamentation contributing to the creation of abstract color terminology. In the Berlin & Kay approach, abstraction involved the denial of materiality and materiality was thus excluded; only abstract linguistic evolution was aimed at.

However, even in the era of the wide-spread application of the Berlin & Kay Theory, in the treatment of the earliest languages as evolutionary stages, materiality was unavoidably accepted. Thus, while philologically included, it was theoretically denied in the case of Ancient Egyptian “white” = “silver” and “green” = a mineral or stone, as well as with Sumerian “white” = “silver” and Akkadian “red” = “carnelian” [5]. Nevertheless – since precisely these concepts are fundamental to the development of lexical color – materiality is increasingly playing a role in contemporary theoretical discussions about ancient color (e.g., [1–4, 6]). Significantly, the story goes back virtually to the origins of writing. (see also Encyclopedia of Color Science and Technology entries on ► [“Evolution of Color Expression”](#) ► [“Ancient Color Terminology”](#)).

The problem is understanding the cognitive relationship between perception and expression as actually experienced in language. For ages, mankind has seen the sun shining in the sky. Yet, in the second millennium BC some Egyptian poets described the visual experience of the evening sun shining on the Nile as “inundating [it] with gold” (Fig. 2) or the morning sun itself “rising golden” in a “field of turquoise” ([6]). Such expressions are rare and seem poetic, but

Materials and the Origins of Abstract Color Naming, Fig. 1 Statue of a standing ram (h: ca. 50 cm) from the mid-third millennium BC elite cemetery at the Mesopotamian city of Ur. Made with gold, silver, copper alloy, lapis lazuli, shell, red limestone, bitumen ([11])

the ancient Egyptians could not express it differently, for they had no independent words for “yellow” or “light blue.” Thus, in a flight of poetic fancy, someone used the precious materials with which the Near Eastern elite had become familiar (Figs. 1, 2, 3, and 4) to describe something that mankind had experienced daily for ages – but had never been put into linguistic expression using abstract words for color, because there were none. And this completely new – but unfinished – solution would endure for another millennium. In Egyptian, the first references to the “sky” as having a color itself are Greco-Roman. By contrast, the first reference to sun as being golden lies in the first half of the third millennium BC.

Earlier, when defined, the sky was turquoise or lapis lazuli (rather than having a color itself) – and this usage only ended during the first centuries AD. Lapis lazuli and turquoise were treated as

Materials and the Origins of Abstract Color Naming, Fig. 2 The Nile in the evening with the sun inundating the river with gold, as expressed by an ancient Egyptian poet. Note that the sky too is golden; the concept of sky and water being “blue” only came after millennia of confrontations with the irregularities of reality and the development of linguistic expression, which contributed to the gradual emergence of abstraction whereby water and sky “became (normally) blue”

precious stones; from the late third millennium onward, gold and lapis lazuli had prices higher than silver (which served as money). The statues of the gods in the temples were made of granite, but also such of materials, some of which were the origins of what later became color words, some merely served to identify “brightness,” and Plato considered “bright” to be a color.

Sumerian “white,” “bright,” and “pure” were linked to silver *kù-babbar*, which was the “(pure) white metal” and was then understood as “white” (*pešû*) in Akkadian. In earlier Egyptian (*ḥdj*) was the word for silver and “white.” In Greek, silver played a role in “shining” (*argos*). Other materials, such as jade (Fig. 4) may have influenced the

Materials and the Origins of Abstract Color Naming,

Fig. 3 Silver hair pin (h: ca. 25 cm) from the mid-third millennium BC elite cemetery at Mesopotamian Ur; silver, lapis lazuli, carnelian, gold, shell, red limestone ([11]). Silver tarnishes and thus “brightness” is lacking today

choices without leaving many traces. Although they did not invariably lead to color names, the materials played a role in the formation of the understanding of color, as can be seen in the earliest languages.

These particular types of materials were largely used only by humans during the last 10,000 years (Bar-Yosef Mayer, Moutsiou, Warburton in [2]), and in the earliest languages, they were rarely used as color words – to the degree that Schenkel ([7, 8] and in [2]) probably correctly disputes that these words played an important cognitive role in the ancient Egyptian expression of color – regardless of developments in other languages later.

Schenkel thus dismisses their importance, whereas Warburton uses exactly these as prominent cases of words, which became color terms when the materials and related words wandered. The word “cyan,” a “blue” in English, owes its origins to Classical Greek *kuáneos*, of which the Modern Greek variant *kuano* is still used for

“blue.” A process of linguistic exchange gave birth to the abstract color term *kuáneos*, but only in Classical Greek where *kuáneos* means “dark blue” or “dark.” Derived from *ku-wa-no*, which in Mycenaean Greek Linear B meant “(dark blue) glass (paste)” (Fig. 6), the word *ku-wa-no* itself was derived (via Ugaritic and/or Hittite) from *uqnû*, an Akkadian word, which was itself originally a loan coming from some other, older, unknown language where it was the name of the mineral lapis lazuli (which was the meaning in Akkadian). In Sumerian, Egyptian, and Akkadian different terms for the name of the stone were also used for glass and dyes of a blue color. The French *azur* (*la couleur du ciel*) likewise owes its origins to lapis lazuli, but through the Persian word *lâzaward* ([14]).

Likewise, relatively late in the history of the development of color terminology, in Classical Greek, *xrusós* (literally “gold”) and words related to it (e.g., *xrúseos*) can mean “golden” or “yellow”; its predecessor in Mycenaean Linear B was *ku-ro-so*, which was more closely related to the material. The word itself is related to Akkadian *hurāsu* (literally “gold”), which was itself usually restricted to the material, but things could be “like gold” in color. In Akkadian, the nouns lapis lazuli (*uqnû*, above) and carnelian (*sāmtu*; related to “redness,” “red” in Akkadian) appear regularly together in the same texts, along with *hurāsu* and *hurāšānû*, “gold” and “golden” (as colors and as jewelry – so that both hues and stones are meant). Thus, the Greek was building on earlier usage, and Mycenaean reflects an intermediate phase.

Loan-concepts reveal loanwords, etymologies, and materials. Pronounced in modern Danish, *guld* (“gold”) and *gul* (“yellow”) are virtually identical – and both linked to English “gold” and “yellow” as well as German *Gold* and *gelb*. In several languages therefore, the word for “gold” implies color associations mostly from the “yellow” portions of color space but can also imply “orange” (and even “red”) areas of color space – and also “bright.” Ancient Chinese *jīn* (literally “gold”) did not designate a color so much as “bright, shining” when used figuratively [10]. The Ancient Egyptian *nb.w* is not related to

Materials and the Origins of Abstract Color Naming,

Fig. 4 Idealized typical European Neolithic axe of jadeite (l: ca. 20 cm) dating to the mid-fifth millennium BC; luxury items of Alpine jade were spread from the Atlantic to the Black Sea coast ([13]), where the earliest lozenge-shaped gold beads were found (virtually identical to, but antedating the third-millennium beads of Fig. 5 by some two millennia). Chinese use of green jades paralleled the beginnings in Europe, but did not stop; Mesoamerican usage came much later, and maintained the tradition. Conceptual

exchange where material, form, and hue were symbolically linked took place in a cultural *koiné* exceeding the spatial and temporal zones generally incorporated into current research: one early greenstone axe was found in Tasmania (Warburton in [2]); one of the earliest is from Neolithic Syria and dates to ca. 10,000 BC [12]. The conceptual traditions binding form, hue, and material antedate the known linguistic phenomena – and therefore transgress the boundaries of known languages, as elaborated in the text

Materials and the Origins of Abstract Color Naming,

Fig. 5 Necklace (each bead l: 2 cm), mid-third millennium BC elite cemetery at the Mesopotamian city of Ur ([11]). The beads visible here are lozenge-shaped, alternating red (carnelian), yellow (gold), and blue (lapis lazuli). A similar set of lozenge-shaped beads – with gold, carnelian, turquoise, and lapis lazuli (i.e., yellow, red, dark blue,

light blue/light green) was found on a bracelet from Egypt one thousand years later (fifteenth century BC). The earliest gold beads of this type were found in Varna on the coast of the Black Sea (4400 BC); a necklace of similar lozenge-shaped beads made of a green stone, dating to the third millennium was found on the Greek island of Naxos

Materials and the Origins of Abstract Color Naming,

Fig. 6 Sketch of a Bronze Age glass ingot (ca. h: 7 cm, Ø 15 cm) from a shipwreck in the eastern Mediterranean, ca. 1300 BC. The glass was probably manufactured in Egypt (where lapis lazuli was called *xsbdfj*), but in the

Mediterranean was probably sold as *uqnû*, the Akkadian word for lapis lazuli, giving rise to Ugaritic *iqnu* and Mycenaean Greek Linear B *ku-wa-no*, meaning “glass.” The word lives on as “cyan”

these Chinese, Semitic, and Indo-European words, but mainly designated the material – yet occasionally the color “yellow” (as noted, above, of the sun) cf. Fig. 2.

For millennia Greek maintained a couple of words for “yellow,” neither of which was distinctly “yellow” – while also using “gold.” The earliest languages thus did not know abstract “yellow” and associated “gold” with the gold (en) metals, but somehow color and material were related and over time led to the linguistic partitioning reflected in, e.g., English. The strong color significance of gold, familiar today, is probably related to the transfer of the word (along with the material) through space and time.

The Akkadian color term *xašmānum* for “blue-green” or “light blue” ([6]) was itself a loanword from Egyptian, designating the light blue or purple stone “amethyst.” Although the Egyptian *ḥsmn* is not a color term, the Egyptian word was adopted as a color word in Akkadian. But the Egyptian was not used as a color word in the Mycenaean world – despite massive imports of the actual stone amethyst from Egypt (Warburton in [2]). Using the Egyptian word was superfluous as other – Levantine – imports gave the Mycenaeans *po-pu-re-jo*, which went into Classical Greek as *porphúreos* and survives in “purple” today. That the Greeks understood the color as being more red than blue is clear because the Romans treasured the stone porphyry. Both amethyst and porphyry are found in Egypt, and thus it is curious that the original – Egyptian *ḥsmn* amethyst purple – hue associated with the word in English today seems to have survived the mutations, despite the fact that the reddish hue associated with the Greek term *porphúreos* – which is etymologically the origin of the modern word – was different.

Although vegetation is known to be “green,” the Egyptian *wādj* (green) is frequently associated with a classifier signifying a stone. Although the Egyptian *wādj* is related to the Akkadian *warqu*, the category centroid, or focus, of the Egyptian term was in “green” and neither “green-yellow” nor “green-blue” – and not “yellow” (Schenkel in [2, 8]). By contrast, the Akkadian *warqu* denoted both “green” and “yellow” appearances and was

used to describe both vegetation and gold; it definitely did not mean “green-blue” or “green-yellow”. However, while “green” was – with a loanword – linguistically demarcated in Akkadian and Egyptian, and the Egyptian linked to a stone; dark green stones are known, but not common in Ancient Near Eastern jewelry.

It is therefore odd that the Akkadian and Egyptian are related in a fashion which suggests both can be traced back to an older word, and that the Egyptian is linked to a stone. Neither of the terms is a loanword from the other language, the Egyptian having changed the /r/ → /ā/ before the literate era. The modern European terms “green,” *grün*, and *grøn* share parts of the root as do *viridis*, *vert*, and *verde*. Thus, in *grün* and *vert*, contemporary German, English, Italian, and French bear traces of different elements, which probably go back to before third millennium BC Akkadian *warqu* and Egyptian *wādj*, and are related to them. All these would therefore apparently go back to an older Pre-Indo-European word (*√qrw or *√wrq?) in an unknown language, antedating the invention of writing and never recorded. Unrelated Sumerian *gin*, likewise inherited from Prehistory, may have meant “axe.” Curiously, when the Indo-Europeans arrived in Europe, the earlier population was dispersed and the practice of using ritual axes made of jade ceased ca. 3000 BC. Yet the original Neolithic stones were familiar before then, and the original word may therefore be derived from a Pre-Indo-European European Neolithic designation for “jade,” “axe,” or “greenstone” (Fig. 4).

When the celebrated Levantine organic “purple” dye (the organic product leading to the modern word, but producing a “red”) entered the Mycenaean world, the Mycenaeans also apparently adopted the custom of manufacturing the dye themselves, but continued to use the loanword. In the case of the famed purple dye, the cost was apparently so high that it was understood as a luxury itself. By contrast, when the Egyptians and Babylonians manufactured glass themselves, they used foreign loanwords meaning “lapis lazuli” (*xsbaj* and *uqnū* respectively) to designate the glass they themselves produced; Thavapalan makes the same point for calcite and yellow glass

([2, 3]). Thavapalan stresses brightness, while Warburton favors recognizing the contrasting hues distinguishing gold, silver, lapis lazuli, carnelian, turquoise, and jade as the reason that the names of the stones were applied to glass, faience, and dyes.

An Akkadian “red,” *ruššu*, is probably the same as Greek *eruthrós* and Italian *rosso*. The Mycenaean Greek Linear B *e-ru-to-ro* is doubtless the same word as Classical Greek *eruthrós* – and will be related to *ward*, the word for “rose” in Arabic and *vr̥dhi*, a similar term in Sanskrit. It is possible that *rwdj* was a red in ancient Egyptian, thus related to Akkadian, Greek, Italian, Arabic, and Sanskrit – but Schenkel disputes this (see in [2, 7, 8]; also [6]). Yet, even if details require modification, the principle is clearly that the ancient concepts moved between languages.

Beyond that are the colorful materials used by the Mayas, Chinese, Europeans, Egyptians, and Mesopotamians that did not invariably enter into color terminology, but played a major cognitive role in art: ivory, shell, obsidian, black granite, red limestone, and agate are among those that do not figure prominently (or at all) as color terms. Other such materials which were used prominently, but did enter into terminology were ocher, carnelian, gold, and amethyst.

There is an enormous difference between (a) the use of precious materials as the foundation of a color terminology and (b) the role of color in the craftsmanship of manufacturing art, where words appear for pigments, but did not become “color-terms.” In the earliest documented languages, in Egypt and the Near East, inorganic materials were largely used for producing pigments, for practical reasons (and the hues linked to the more precious materials being imitated, e.g., Blom-Böer in [2]) while in the later Mesoamerican tradition inorganic pigments were used on stone, but organic pigments were employed when applying color to organic materials (as opposed to stone), with strong symbolic connotations ([4], Dupey-García in [1]). By the first millennium BC, dyes with organic components had become more important in the Near Eastern

world, but the formative vocabulary had been determined by the inorganic materials.

Precious Materials, Loanwords, Abstraction, and Grammar

Language interaction was important in trade as the valuable materials were sought out, leaving traces in disparate ways, where forms (e.g., axes and lozenge-shaped beads) also played a part. Thus, jade, carnelian, silver, lapis lazuli, and gold all played roles in the development of the use of color. Via art, these filtered into elite consciousness and the earliest known languages, with perceptions and expressions feeding into the development of color terminology. Materials eventually led to abstract color words, but usually only in the languages into which they were imported, a process beginning in the third millennium BC, but only having systematic effects from the first millennium BC onward. Through the second millennium BC, many expressions of color are rooted in materials – most of which were later eclipsed with abstract words created and adopted through exchange.

One of the greatest obstacles to understanding the nature of the earliest origins of ancient color terminology (in the Ancient Near East) and the origins of abstraction (in Greek and Chinese) is appreciating that in the earliest usage, the ancients did not classify the world according to modern terminological divisions of the diversity of visible light, but rather that they initially used their perceptions of precious materials to express many of the colors they perceived. Thus, their understanding of color was rooted (in the sense of hue, saturation, brightness, intensity, hardness, and frequently form) in the materials – which properties they then applied to other domains. This eventually created the basis for abstract color terminology. However, the origins render the discussion complicated. (See, e.g., [1–3, 6, 9, 13]).

In Akkadian, Chinese, and Greek, color words are largely adjectives. Some of the Greek terms can be traced back to Near Eastern materials. Of the languages discussed here, Chinese is the only

language with a completely abstract color vocabulary, where hues and terms match, more or less. Although silk appears as a component in the writing of some color words in Chinese, even as a component, in China jade played an even more marginal role. Thus Chinese color terms never bore close primary relations to precious, natural object categories; the evolution of Chinese color vocabulary differed fundamentally from that of the West – but the results are similar to those in Greek (probably implying diffusion rather than convergence).

The Mediterranean languages usually had a word for “color” as a phenomenal experience; however, the words were not restricted to a single meaning in terms of hue. In Egyptian, the word *jwn* is probably derived from the designation for a “vein” of ore (meaning the material color which was visible), but it also meant “character” of a person in the figurative sense (what was hidden under the surface, but confusingly also skin itself). Although in later Chinese the suffix *sè* is frequently attached to color words, in the earliest Chinese no term for color as such has been discovered.

In his list of Indo-European etymologies, Shields ([15]) suggests that the abstract terms “bright,” “gleaming,” etc., are the basis for many words that eventually became abstract color words. However, Chinese terms for “bright” or “clear” such as *míng* and *qīng* did not give rise

to color words. Over time, Classical Greek *glaukós*, initially denoting “gleaming,” did acquire a meaning of “bluish green” or “gray” – but never became a stable color term. Sumerian *šuba* means “shining” but never became a color term; *tjhn.t*, an Egyptian word for “gleaming” or “dazzling,” never became a color word. In ancient languages, there are many more words for “gleaming,” “shining,” “brilliant,” “bright,” etc., than can be inventoried (see also Encyclopedia of Color Science and Technology entries on ► “Evolution of Color Expression” and ► “Ancient Color Terminology”).

Many of these terms, like *tjhn.t*, *hsmn*, and *šuba* probably originally designated precious stones, and the origins of “bright” may well lie in this domain (rather than abstract categories). Thus, through diffusion, precious materials (rather than abstract “brightness”) are more likely the origins of both “brightness” and abstract color words. Gold, silver, carnelian, turquoise, and lapis lazuli suggest that, via hues, a select few materials bridged the way into abstraction as color terms; others served a similar role in the “bright” and “dark” categories. Along with hardness, form, brightness, and intensity, hue was probably decisive in determining the names and colors that were developed or maintained; abstract “bright” is not evident.

Figure 7 approximates the relationships between color appearances and color terms.

M

Materials and the Origins of Abstract Color Naming, Fig. 7 Examples of physical materials related to ancient color terminology displayed in congruent regions of a Munsell Color Chart

Summary

Through art and language, precious materials played a decisive role in the early understanding of color. Appreciation of a wider spectrum of colors (than the dark/bright/red distinction which must be more than 10,000 years old) is a product of social developments in the last 10,000 years – and mostly in the last 5000 years. A tradition of luxurious artwork began in the Ancient Near East, and brought color into the lives of the members of the elite, at a time when book-keepers counting stones could also be poets. Over time, the manufacture of artificial pigments used as textile dyes and in the production of glass brought color to increasing proportions of the population. Before this, the trade in semi-precious stones and precious metals contributed to the development of abstraction as the materials changed hands, frequently bearing the earlier name as a loanword, which was incorporated into the language of the recipients – and used to designate both the artificial materials and the colors in a fashion which had not hitherto been normal. In this fashion, materials contributed to the emergence of abstract color terminology – but in the languages of the recipients (initially certainly Chinese and Greek) and their successors, such as English and German, rather than in the languages where the earliest terminology developed (in Egypt and Mesopotamia).

Mauveine

Harold S. Freeman

Wilson College of Textiles, North Carolina State University, Raleigh, NC, USA

Definition

Mauveine, also known as Perkin's violet, mauve, and aniline purple, is generally acknowledged to be the first synthetic dye, having been discovered by William Henry Perkin in 1856 [1]. As shown in Fig. 1 below, Mauveine is a cationic dye having an acetate or sulfate moiety as a typical counterion. It is also an azine dye belonging to the Safranine class and was derived from oxidation of aniline in combination with a mixture of *ortho*- and *para*-toluidine [2]. Interestingly, Mauveine was found to give on silk fabric a regal purple color that was comparable to the shade produced by the natural dye Tyrian purple. It was the dominant synthetic colorant in the marketplace until 1873, giving way to triarylmethane dye fuchsine (rosaniline), which was brighter and more easily made.

Historical

The synthesis of Mauveine began in 1856 when the 18-year-old William Henry Perkin attempted to produce the antimalarial agent quinine ($C_{20}H_{24}N_2O_2$) from *N*-allyl-*para*-toluidine ($C_{10}H_{13}N$). Bearing in mind the molecular formulas of the starting and target compounds but

without a knowledge of their molecular structures, it was anticipated that quinine was an oxidative dimerization step away from the starting compound. The brown powder obtained as the product of this reaction lacked any quinine. Likewise, Perkin did not produce quinine following oxidation of the parent compound aniline using potassium dichromate. However, the black solid obtained gave a purple solution when hot ethanol was used to help clean the glassware employed in this synthesis [3]. Subsequent analysis of this purple product revealed it could be useful as a dye for silk and other textile fibers [4]. With this in mind, Perkin patented his new technology and in 1857 he and his family established a company (Perkin and Sons) to produce the dye on an industrial scale. The dye was originally called aniline purple. Two years later, their product was called mauve in England, from the French name for the mallow flower, and chemists subsequently referred to it as Mauveine [5]. During 1859–1861, Mauveine was the leading dye in the fashion industry.

Dye Formation

The origin of Mauveine was an act of serendipity in two respects: 1) an entirely different but highly useful product was the outcome of the experiment conducted and 2) pure aniline was not used, as it would not have produced Perkin's dye. As the structure of Mauveine indicates, the formation of Mauveine occurred because nineteenth-century aniline contained significant amounts of *ortho*- and *para*-toluidine impurities, which is illustrated in Fig. 2. Commercially, the aniline mixture is dissolved in sulfuric acid and water in approximately a 1:1:2 ratio, then potassium dichromate is added. In the Fig. 2 illustration, the Mauveine structure is generated from two equivalents of aniline and one equivalent each of *ortho*- and *para*-toluidine.

In the nineteenth century, the Perkin and Sons production of Mauveine was actually a three-step process, beginning with commercially available benzene, as shown in Fig. 3. The goal of steps 1 and 2 was to produce large quantities

Mauveine, Fig. 1 Molecular structure of Mauveine, where X = acetate, sulfate

Mauveine, Fig. 2 Illustration of Mauveine formation from mixed anilines

Mauveine, Fig. 3 Steps required to obtain aromatic amines used in Mauveine manufacture

Mauveine, Fig. 4 Examples of structures reported for Mauveine

of the anilines necessary for dye manufacture. At that time benzene contained a significant amount of toluene, which gave a mixture of nitrobenzene and isomeric nitrotoluenes. Reduction of the nitro compounds gave the required aniline mixture. Mauveine formed when the mixture of aromatic amine was treated with $K_2Cr_2O_7/H_2SO_4$.

Structures

In view of the possible combinations that can occur when aniline, ortho-toluidine, and para-toluidine react with each other in the oxidation step, several “Mauveine” structures have been reported. Examples are **A–E** shown in Fig. 4, which include products containing aniline or

para-toluidine built into the central ring and/or attached to an external ring. Until the work of Meth-Cohn and Smith [6], it was often reported that structure **D** corresponded to the main component of Perkin's Mauveine. However, the 1994 isolation of the principal components of an original dye sample followed by spectroscopic analyses revealed dye **A** to be the major component, with dye **E** the secondary component. These results are consistent with Perkin's recognition of the importance of *ortho*- and *para*-toluidine in the color and properties of Mauveine. Meth-Cohn and Smith also pointed out that structure **D** would require *meta*-toluidine as a key precursor, despite its very minor contribution (4%) to the product mixture following the nitration and subsequent reduction of nitrotoluenes. Compared to dye structure **A**, structure **E** contains an additional *ortho*-toluidine moiety, which is consistent with its significant presence in the anilines mixture used in dye manufacturing. A method for reproducing the synthesis of Perkin's commercial Mauveine has been reported [7]. The yield was quite modest but sufficient to validate the method.

Further Comments

Mauveine is extraordinary not only as the first synthetic and commercial dye but also for its overall contribution to the field of organic chemistry. This important discovery gave birth to the chemical industry and subsequently the pharmaceutical industry, in that the technology developed to manufacture this dye on an industrial scale proved invaluable in this broader context. Similarly, the recognition of its ability to dye silk, and later other fiber types, had a profound impact on the nineteenth-century textile industry. The invention of no other synthetic dye has been more impactful.

Maxwell, James Clerk

Renzo Shamey

Color Science and Imaging Laboratory, College of Textiles, North Carolina State University, Raleigh, NC, USA

Maxwell, James Clerk

Biography

James Clerk Maxwell was born on June 13, 1831, in Edinburgh, Scotland, to a family of comfortable means and was the only child of his parents. He is considered to be a pioneer in several fields of science. Maxwell contributed greatly to the field of optics and the study of color vision and helped lay the foundations for practical color photography. Over a period of 17 years from 1855 to 1872, he published a series of papers concerning the perception of color, color blindness, and color theory [1]. He died in Cambridge at the age of 48 of abdominal cancer in 1879 [2].

Maxwell had a keen intellect and an unquenchable curiosity from childhood. Maxwell's formal schooling began unsuccessfully, and it is reported that he was treated harshly by his private tutor for being slow and disobedient [3]. He was then sent to the prestigious Edinburgh Academy to continue his education. At the age of 13, he won the school's mathematical medal as well as the first prize for English and poetry. At the age of 14, he wrote his first academic paper on *Oval Curves* which was presented, on his behalf, at the Royal Society of Edinburgh.

When 16 years old Maxwell was enrolled at the University of Edinburgh. There, among many other things, he learned about disk color mixture (Fig. 1) from one of his professors, James D. Forbes (1809–1868), who was working on a color classification system. During his undergraduate studies Maxwell also examined the properties of polarized light [4]. At age 18, he contributed two papers to the Transactions of the Royal Society of Edinburgh. One of these, *On the Equilibrium of Elastic Solids*, laid the foundation for an important discovery on the temporary double refraction produced in viscous liquids by shear stress [5]. In October 1950, Maxwell moved to the University of Cambridge's Trinity College where he graduated in 1854 with a degree in mathematics. He stayed at the Trinity College after graduation until 1856 when he accepted the position of professor of natural philosophy at Marischal College in Aberdeen [6]. In 1858 he married Katherine Mary Dewar who regularly assisted him in his experimental work. In 1860 he was granted the

Maxwell, James Clerk, Fig. 1 Young Maxwell demonstrating one of his spinning color wheels

chair of natural philosophy at King's College in London. He stayed there until 1865, working primarily on electromagnetism. He and his wife returned to his inherited estate in Glenlair, Scotland, until he became the first Cavendish Professor of Physics at Cambridge University, where he stayed until his untimely death. Maxwell's famed equations on electro magnetism, "*Dynamical theory of the electromagnetic field*" were delivered to Michael Faraday at his residence at the Royal Society in 1864, where as a young man Faraday himself had tried on several occasions to get his work noticed. While the two men were not close, they strongly respected each other. He is considered to be the "father of electromagnetics." He is also the inventor of a thought experiment on thermodynamics, resulting in what is known as "Maxwell's demon."

Maxwell and Color

The nature of perception of color was one of Maxwell's interests which had begun in Scotland. Using an improved version of a disk mixture

Maxwell, James Clerk, Fig. 2 Reproduction of the Scottish tartan image using the photographic images and color filters employed by Maxwell and Sutton in their demonstration in 1861

apparatus, he demonstrated that white light results from a mixture of red, green, and blue light. His paper *Experiments on Colour* was a fundamental study of the color-mixing principles and was presented to the Royal Society of Edinburgh in 1855 [3]. In the following years he built a visual spectrometer in which he could mix and adjust spectral lights. The results of his own and his wife's mixture data, published in 1860, demonstrated that only three primary lights are required to match any spectral or composite light. In the same year he was awarded the Royal Society's Rumford Medal "for his researches on the composition of colours and other optical papers."

Based on his trichromatic theory, Maxwell proposed in the late 1850s a method for practical color photography. He suggested that if a scene is photographed three times separately but using red, green, and blue filters, and the resulting black and white transparent images are then superimposed on a screen using projectors equipped with similar filters, the result would be a full color reproduction of the image as seen by the human eye. Together with the photographer Thomas Sutton, he demonstrated this in 1861 at the Royal Society. As the image of the Scottish tartan shows, due to the fact that the filters were less than optimal, the outcome was less than

perfect, and commercial color photography required another 45 years of invention (Fig. 2).

Mayer, Tobias

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Tobias Mayer, born February 17, 1723, in Marbach, Germany, a mathematician, astronomer, cartographer, and physicist, was the only child of a fountain builder and his wife. Mayer was 10 years old when his father passed away, and he grew up in impoverished circumstances in the nearby city of Esslingen, spending some time in an orphanage. He taught himself mathematics and in his later teens earned some money teaching it. Mayer also showed early interest and capabilities in drawing and painting. He moved to Augsburg to obtain more training, working for the engraver and publisher J. A. Pfeffel. At 18 he wrote and published an elementary book on mathematics and at 22 a much more detailed work on the same subject [1]. His capabilities and the fact that he had designed an accurate map of Esslingen, later published, provided for him in 1746 an offer to join the firm of the cartographer Homann in Nürnberg, at the time perhaps the most important map publisher in Europe. In 1751 he married Maria Gnüge, and a year later their son Johann Tobias was born, in his later life a mathematician/physicist. In the same year Tobias Mayer's reputation as a scientist resulted in an offer of a professorship in economy and mathematics at the University of Göttingen, where he remained until his untimely death on February 20, 1762 due to a typhus infection. In 1754 he also became the supervisor of the Royal Observatory of Göttingen, built some 10 years earlier. His major scientific achievements are a data table of the moon and highly detailed drawings of the surface of the moon based on a new methodology to achieve high accuracy and the development of a new much more accurate methodology for the determination of longitude. The latter effort resulted in his widow receiving a 3,000-pound Sterling Award from the British Parliament. One of the craters of the moon is named "T Mayer" [2].

Major Accomplishments/Contributions

Mayer's combined interests in mathematics and painting resulted in an attempt to develop a

mathematical model of the relationships between colors. Not accepting, on practical grounds, Newton's idea of seven main colors in the spectrum, Mayer decided to base his model on the painter's primaries yellow, red, and blue. He placed these at the corners of an equilateral triangle and divided the lines between them into 12 presumably perceptually equal parts which, he assumed, could be represented by corresponding weights of the pigments used as primaries. He believed that these grades represented perceptually visible and comparable differences. The interior of the triangle is filled with colors that are mixtures of all three primaries. All of them are identified numerically, such as $r^8g^2b^2$ consisting of eight parts of the R primary and two parts each of the G and B primaries (Fig. 1) [3]. The 91 colors of the triangle of Fig. 1 can also be lightened or darkened, by addition of white or black pigments, again in twelve increments each. As these scales must end in single white or black, he gave the resulting solid the form of a double triangular pyramid, with a total of 819 defined colors [3]. In his German translation of the original Latin text, H. Lang defined Mayer's system as attempting to meet five then novel conditions: (1) All possible object colors are represented. (2) All colors are the result of mixtures of three primary colors. (3) Each color is represented by a triple number indicating the content of the three primaries. (4) The totality of all colors in the system is contained in a three-dimensional color solid. (5) The differences between neighboring colors correspond to perceptual differences [4].

Mayer presented his ideas in 1758 in a public meeting of the Society of Sciences in Göttingen, a report of which was published in the newspaper *Göttingische Anzeigen von gelehrten Sachen* (Göttingen reports on scholarly matters) some three weeks later [5]. This report was the basis of J. H. Lambert's work on his triangular color pyramid [6]. Mayer had not done much experimental work to implement his system. As pointed out by Lambert, Mayer had not been aware of the varying coloristic strength of the three primaries, requiring consideration for the purpose of obtaining perceptual uniformity.

Mayer, Tobias,

Fig. 1 Central plane of Mayer's double triangular pyramid color solid

In 1958 Mayer also invented a new coloration method for prints. He proposed, and produced an example of, the coloration to consist of sections of wax containing different amounts of pigments to achieve different colors [7]. Multiple prints could then be produced from the wax collage. The idea proved to be too complex to be practical and was not pursued after his death.

Mechanisms of Color Categorization

Yasmina Jraissati

American University of Beirut, Beirut, Lebanon
Ronin Institute, NJ, USA

Synonyms

Factors of color categorization; Origin of proto-types; Origin of boundaries

Definition

Color categories vary across cultures, but there are important regularities. Where do these come from? Color categories are graded and feature a

focal color or prototype. In the literature, for a long time, the question pertaining to the origin of color categories was conflated with the role and nature of prototypes. This entry goes over the main answers to this question.

What Is Color Categorization and Why It Matters

Some have claimed that categories are the building blocks of cognition [1]. Our experience of the world is temporal, featuring a series of events and sensory experiences. Yet, we are able to sort and organize these sensations into groups called categories. In the case of color, we categorize color experiences on the basis of the similarity of their chromatic qualities. The way colors are categorized is not trivial. Apart from their use in memory, action, and communication, categories are also useful in inference and induction.

While I have a concept of red, a mental representation that encompasses contents like “red strawberries are sweet,” the category RED is not a mental representation and consists of a group of items in the world, to which the label “red” applies. However, things that are red at different degrees are all equally called “red.” How then, does an agent categorize? More generally, the question pertains to how a given categorization system emerges ([2] for a recent review).

Graded Membership and Prototype Theory

According to Rosch, there are two cognitive principles of categorization: cognitive economy and perceived world structure. The generally accepted hypothesis, which continues to inform recent categorization models, is that a category system provides maximum information with the least cognitive effort: There is a trade-off between having a large number of categories with as fine discriminations between categories as possible and having a small number of categories that will reduce cognitive effort. The cognitive economy principle tends toward reducing the infinite

differences among objects to proportions that are cognitively and behaviorally usable. On the other hand, the perceived world structure principle tends to gather information from the world, granting that the world possesses high correlational structure – e.g., wings tend to co-occur with feathers more than with fur.

Given perceived world structure, it follows that certain cues predict category membership: A given cue x is a predictor of a category y (e.g., feathers are a predictor of birds). As the frequency with which cue x is associated with category y increases, the validity of x as a predictor of y increases. The validity of x decreases as the frequency with which x is associated with categories other than y increases (e.g., fur is *not* a good predictor of birds). Consequently, the entire category has as a cue validity: It is the sum of the cue validities of all the attributes of the category. Thus, by definition, a category with high cue validity will be more differentiated from other categories than a category of lower cue validity.

There are two dimensions along which objects can be categorized: The “vertical” dimension refers to the inclusiveness of a category, while the “horizontal” dimension refers to the segmentation of the world at the same level of inclusiveness. So, for example, bird and robin are on the same vertical dimension (a robin is a kind of bird), while cat and dog are on the same horizontal dimension. On the vertical dimension, members of superordinate categories (e.g., mammals) have lower total cue validity, as the number of shared attributes is low. Members of subordinate categories also have lower total cue validity (e.g., Dalmatians), as the number of attributes shared with other categories (e.g., Beagles) is high.

The cue validity is maximized at the so-called *basic* level (e.g., dog). Similarly, on the horizontal dimension, within a category, some members of the category have higher cue validity than others and are better predictors of the category. These members of the category share more attributes with more members of the category and are, therefore, more similar to a larger number of category members than others. These are most representative, *prototypical* members of a category.

Basicness and prototypicality result, according to Rosch, from the two cognitive mechanisms of cognitive economy and perceived world structure. Prototype theory describes a categorization process and the resulting category structure. It also accounts for the cognitive advantages that prototypes have in comparison to other category members (e.g., typicality effects: prototypes are processed faster, learned faster, and produced faster). Prototype theory does *not* however offer an ontology: Prototypes should not be reified or identified with a specific category member or mental structure. People's judgments of goodness of membership is what defines prototypes. Thus, prototypes, and also categories, are context dependent.

Color Categories

In 1969 Berlin and Kay published a seminal monograph, *Basic Color Terms: Their Universality and Evolution* [3], in response to Boas [4] and Whorf [5], who had argued that notwithstanding the universality of human perceptual apparatus, color lexical categories varied across languages. In their perspective, language is the reason why we categorize the way we do [6, 7].

Led by the simple observation that some color terms in English translated well in many languages, Berlin and Kay conducted a cross-cultural naming task. They compared a total of 98 languages and made the following claims: (1) There is a set of 11 universal basic color categories; (2) color terms emerge in lexicons following a constrained evolutionary sequence.

These claims are somewhat controversial because what counts as a "basic" color term may be intuitive but is difficult to define in a way that is not ad hoc [8–10]. Also, different languages may have different numbers of color terms, but this is not enough to talk of lexical "evolution." The remarkable observation in *Basic Color Terms* (BCT) and the subsequent World Color Survey (WCS) is that unrelated languages, featuring the same number of basic color terms, have categories that partition color space in similar ways. Thus, a language featuring only four basic color terms and

categories, usually features color terms referring to the category BLACK (extending over dark colors), WHITE (light colors), WARM (red, yellow and orange), and COOL (blue and green). A language featuring six basic color terms will typically have terms referring to BLACK, WHITE, RED, YELLOW, BLUE, and GREEN.

Where Do Prototypes Come from? The Perceptual Account

As in the case of birds or dogs, color categories feature a graded structure. Take the category we call "blue" in English. Some colors are focal or most typical of "blue," while others could be labeled "green." In a two-dimensional representation of color (Fig. 1), categories are represented as an irregularly ovoid area (Fig. 2). Focal colors figure toward the center of the category: This is where membership is highest (Fig. 3), and where typicality effects can be observed [11, 12]. Membership gradually decreases and is lowest at the periphery [13].

What is the role of prototypes and where do they come from? Because of the sensory nature of color categories, and encouraged by the color vision science of the 1970s [14], Rosch hypothesized that color categories were shaped by naturally determined prototypes [15]. Thus, in the case of color, Rosch supported the reification of prototypes. It was believed that the output of the second stage opponent color processing mechanism yielded none other but Hering's unique hues – white, black, red, green, yellow, and blue [16]. Interestingly, WHITE, BLACK, RED, YELLOW, GREEN, and BLUE are the first six categories of the BCT's evolutionary sequence. The suggestion was therefore that basic color categories' prototypes resulted from these neuronal responses [17].

Ecological Constraints

A different account of prototypes is sought in ecology. Based on images of natural scenes, amounting to 10,000 pixels, a process of

Mechanisms of Color Categorization, Fig. 1 The Munsell array used in the WCS

Mechanisms of Color Categorization, Fig. 2 Mode map of the French lexicon [42]

categorization was modeled through grouping natural image statistics by a clustering algorithm, with grouping based on the minimum-distance criterion [18]. It appears that the centers of these clusters are most similar to the configuration of natural languages' focal colors. The distribution of colors in the world, as they were experienced in the past would in this approach account for the location of focal colors in color space. Also, a high correlation was found between the order of emergence of cluster centers and the constrained evolutionary sequence offered by the BCT. A trade-off between accuracy in representation and simplicity of the category system is thought to guide the number of categories in a given lexicon (also see [19]).

However the role of ecology in categorization is a complex question, and there is more than one possible direction of influence. It is possible that color distribution in the environment shapes color categorization, but the structure of our perceptual experience might itself result from an adaptation

to ecology. For example, Shepard [20] contended that the reason why light/dark, red/green, and yellow/blue are the dimensions of our perceptual experience has to do with the variation of the color of light. This three-dimensional representation of color may result from an adaptation of our light processing system [21] to a pervasive and enduring feature of the world (also see [22]). This three-dimensional nature of color experiences would in turn translate into categorical perception. Indeed, there is evidence of a form of categorical perception in animals [23]; and when it comes to pre-linguistic human infants, there is also mounting evidence of categorical behavior [24–26].

However, the implications of these observations when it comes to factors underlying human adult categorization are not straightforward. Importantly, English infant categories do not correspond to those of adult English speakers [27]: Unlike adult categories, their boundaries coincide with the cone-opponent dimensions resulting from the second-stage mechanism, which are in

Mechanisms of Color Categorization, Fig. 3 Heat map of membership to “jaune” as measured by consensus in naming. (From [42], unpublished)

fact closer to cherry/chartreuse and orange/teal than to yellow/blue and red/green [26, 28].

Perceptual Mechanisms Are Not Enough

Though it provides a powerful account of color categorization, a biological approach to prototypes faces many challenges. First, we know today, as just mentioned, that the outputs of the second-stage opponent process mechanism does not yield the unique hues at all [28]. Second, reducing prototypes to neuronal responses might account for their universality, but it does not explain lexicon evolution. Third, if prototypes are naturally given, it is surprising why not all languages have categories for each unique hue.

Finally, the biological reduction of color prototypes is conceptually unappealing: If color categories were biologically fixed, there would be no trade-off between maximum information and minimum effort in a given context.

These are the main reasons why subsequent models of color categorization break away from this kind of strong biological approach. In a seminal paper, Regier, Kay, and Khetarpal [29] explicitly aimed at a model that would make room for cross-linguistic variations. Building on a proposal by Jameson and D’Andrade [30], they make use of the idea of the irregularity of perceptual space: Our perceptual sensitivity thresholds are not uniform across the color spectrum resulting into some areas being perceptually more salient than others. Given an endowed capacity to produce

“optimal” categories (members of a category are most similar to each other, and least similar to members of other categories), the irregularity of perceptual space would lead to universal patterns of categorization for various numbers of categories. This model is promising as it is verified for up to six categories ($n = 1, n = 2 \dots, n = 6$), but it does not predict the categorization pattern of $n = 11$ [31], knowing that many languages feature 11 basic color categories or more (e.g., English, French, Turkish, Arabic, etc.).

Connectedly, a series of recent studies has shown that the relationship between perception and lexical categorization was only loose [32, 33]. Testing just noticeable difference thresholds across an isoluminant hue circle in DKL space (which represents sensitivities of the opponent mechanisms), these studies have shown that only two lexical boundaries coincide exactly with sharp dips in sensitivity thresholds, namely, the lexical boundaries “blue”/“green” and “pink”/“yellow” (there was no category for “red” at the selected brightness level). Together, these results suggest that there must be more to lexical categorization than perceptual mechanisms, thereby re-introducing linguistic and cultural factors.

Communication Constraints and Cultural Transmission

It should be noted that linguistic relativism does not deny perceptual constraints: A color category cannot be discontinuous in color space, it can only include neighboring colors in its extension. Also, the same colors are considered as neighboring across cultures: This assumes that humans experience the same continuum, which ultimately results from the overlapping sensitivity ranges of their photoreceptors [34]. The main point of disagreement culminates in the nature and role of prototypes. The contention here is that prototypes result from, and do not precede, category formation, as in Rosch’s initial and general account. That is, in language use, a consensual extension of a given color term stabilizes, and consequently, the prototypical area emerges as an abstraction of a central tendency.

Prototypes should however not be understood merely as centroids that result from the category’s extension: Indeed, category boundaries vary more than focal colors do [35]. Instead, some have suggested that the best examples are most representative, in the sense where prototypes reflect both high similarity to other members of the category and low similarity to members of other categories [36]. This would account both for regular patterns of categorization and for unusual ones. What determines color categories in this view is the functional pressure for informative communication given the structure of color space [37]. From this information-theoretic perspective, efficiency in communication leads to need (reflecting the world’s structure) and precision (resulting from perceptual structure) being connected. Ultimately, this approach suggests that language in communication and perceptual structure both shape color categorization [38].

Thus, it should not be forgotten that color lexica are ultimately a population phenomenon. A seminal study [39] using hundreds of artificial agents and Munsell colors shows that linguistic communication and other non-linguistic social interactions coordinate color categorization, even in the absence of a statistical structure to the data, that is, regardless of the distribution of color in the environment. Other population factors, like birth-death cycles [40], play a role in reaching a consensual and stable categorization system, similar to the ones observed in natural languages. A link between the lifespan of the population and the number of color terms is suggested. Interestingly, birth-death cycles in human societies vary with technological development, and, incidentally, so does the size of color lexicons. The important input of these studies is that beyond communication, cultural transmission might more specifically be at play [41].

Conclusion

Color categories are graded: Some objects have a higher membership degree than others. According

to Rosch, best members of the category are the prototypes, which are taken to result from two principles: Cognitive economy and perceived world structure. In the case of color however, the nature of the prototypes has been debated. The way they are determined is a central question, as it critically connects to the more general understanding of the origin of color categories.

Melanin

Tova N. Williams

Wilson College of Textiles, North Carolina State University, Raleigh, NC, USA

Synonyms

Natural Hair Colorant; Natural Hair Pigmentation

Definition

Melanin is the natural colorant in protein substrates such as hair, but it makes up only a small percentage of the hair fiber’s mass. Two types exist – eumelanin and pheomelanin – which, depending on factors such as concentration, can lead to colors including black, brown, red, and blonde.

Overview of Melanin Pigment

Melanin is a colorant found in biological systems including plants, animals, molds, and mildews, as well as the human body [1]. It is a pigment that is a component of the human eye, skin, and hair. In hair, it is found almost exclusively in the cortex (or the inner region) [1, 2]. Although melanin pigment constitutes less than 3% of human hair fiber mass [3], it plays prime importance in defining an individual. Natural hair color is mandated by an individual’s parents, and thus, is a reflection of one’s ancestry [4]. Natural hair color will change over time – accidentally or naturally. For example, a person experiencing a severe iron deficiency may notice a shift in black to brown color of his or her hair [3]. And as a part of aging, hair will produce less pigment and become gray [5, 6], coarse, and resistant to dyeing [3]. Completely unpigmented hair is white [7], and the scattering of light from the exterior of hair lacking pigment is responsible for its gray/white color [6]. Presently, the mechanisms for hair depigmentation are

Melanin, Fig. 1 Proposed structures of eumelanin and pheomelanin pigments as determined by Gray [3]

being investigated, but it seems the mostly likely causes are hereditary factors.

Melanocytes are cells that secrete melanosomes during hair growth and development [3, 6]. The melanosomes initially contain protein matter (melanoprotein) that can bind melanin pigment [8, 9]. The pigment will eventually be transferred to other cells [3], for example, keratinocytes (or keratin-producing cells) [6, 8, 9]. Fascinatingly, nature only needs two substances – eumelanin and pheomelanin – to produce a variety of shades from black to brown to red to blonde unlike the hair color chemist who requires far more colorants [8]. Eumelanin and pheomelanin (see Fig. 1 for proposed structures) are contained within melanosomes and estimated to be 0.2–0.8 μm in length [3]. They can form aggregates of about 300 nm [10]. Eumelanin gives brown to black shades [1, 3, 6], and the melanosomes housing it have been described as ellipsoidal in shape [3]. Contrastingly, others have described the shape of the melanosomes as ovoidal or spherical with uniform shape and defined edges [8, 9]. Pheomelanin, sometimes referred to as “phaeomelanin” [3], gives red to blonde shades [1, 3, 6, 9]. The melanosomes housing it have been described as spherical [3]. Others have described these melanosomes as moderately

spherical or rod-like [8, 9] and smaller than those of eumelanin [8]. The most dominant pigment seen in the global population is eumelanin [3, 6], found most exclusively in Japanese [8, 9, 11] and Korean hair [11]. On the other hand, pheomelanin is the dominant pigment found in Celtic hair [8, 9, 11]. Black hair contains a higher concentration of pigment deposited in melanosomes, and this pigment is more uniformly dispersed [3]. In fact, the darker the hair, the more concentrated the eumelanin [8, 9]. Melanin particle size and granule density contribute to the depth of shade achieved, while the proportion of the melanin types contributes to the shade itself [12]. Over the lifespan of an individual, the type and concentration of melanin will change [3]. Since not all hair follicles produce the same types and concentration of melanin, variation is even evident spanning the different regions of the body.

Melanins are believed to be amorphous and polymeric. However, their absolute structures have been difficult to determine due to their insolubility [1]. The formation of melanins takes advantage of bifunctional enzymes that catalyze the hydroxylation of phenols and subsequent oxidation of diols to quinones. In the present case, the biosynthetic routes for

Melanin, Fig. 2 Biosynthetic pathways toward eumelanin and pheomelanin [8, 13]

eumelanin and pheomelanin have been proposed to be similar, beginning with a pair of tyrosinase enzyme-induced oxidation reactions that involve the conversion of tyrosine to 3,4-dihydroxyphenylalanine (DOPA) and then to dopaquinone (DQ) [1, 3, 8, 9] (see Fig. 2). Inside the melanosomes, DQ undergoes cyclization to leucodopachrome followed by oxidation to the orange-colored compound, dopachrome. Dopachrome undergoes isomerization to form the carboxylated diol, 5,6-dihydroxyindole-2-carboxylic acid (DHICA), followed by decarboxylation to give

the corresponding indole, 5,6-dihydroxyindole (DHI). A series of oxidation steps produces indolequinone and culminates in oxidative polymerization to give eumelanin [3]. This chemistry has been supported by chemical degradation studies designed to establish DHICA and DHI as key building blocks of eumelanins. For pheomelanin formation, the two-step conversion of tyrosine to DQ is followed by a reaction with cysteine to form a mixture of cysteinyl-DOPA (CD) isomers and then a CD-quinone mixture, which is then converted to benzothiazine and benzothiazol isomers. These

heteroaromatic products undergo polymerization to produce pheomelanin [13].

High-field (600–750 MHz) 2-D (^{13}C and ^{15}N) solid-state NMR spectroscopy has been used to characterize synthetic melanin prepared from ^{13}C and ^{15}N enriched L-tyrosine or dopamine [14]. The goal of this investigation was to label the resulting eumelanins and demonstrate that cell-free polymerization of the two precursors produces melanins with an indole-based aromatic core structure found in natural melanin pigments. While researchers had assumed that synthetic melanins were suitable models of melanin from natural sources, their structural agreement had not been demonstrated directly. Further, the use of solid-state NMR for the analysis helped overcome the investigative challenges posed by these insoluble, heterogeneous pigments.

Melanopic Equivalent Daylight Illuminance

Wout van Bommel

van Bommel Lighting Consultant, Nuenen, The Netherlands

Definition

Illuminance produced by radiation conforming to standard daylight (D65) that provides an equal melanopic irradiance as the light source considered. Melanopic irradiance is the result of the human pRGC response due to its photopigment melanopsin. pRGCs (intrinsically photosensitive retinal ganglion cells) are those ganglion cells located in the retina of the human eye that are photosensitive by means of the photopigment melanopsin.

Photosensitive Retinal Ganglion Cells (pRGCs)

In 2002, Dave Berson and coworkers from the Brown University in the USA discovered a third type of photoreceptor in addition to the well-known cone and rod types [1]. A small part of the already long known ganglion cells in the retina are sensitive for light incident on them. This third type of light-sensitive cell is called “photosensitive retinal ganglion cell”: pRGC. In literature it is also referred to as ipRGC which stands for intrinsically photosensitive retinal ganglion cell. This particular type of ganglion cell transmits signals to the supra-chiasmatic nucleus (SCN), a pacemaker organ in the brain that provides time cues to the body. The SCN, often referred to as the biological clock, controls many body properties with a circadian rhythm (24-hour rhythm). Examples are the heart rate, blood pressure, liver function, generation of new cells, and the production of many hormones. The hormones melatonin and cortisol are of particular importance because they govern sleep and alertness. The free-running rhythm of the SCN varies between individuals from approximately 23.5 to 25 hours. The 24-hour rhythm of natural daylight-darkness synchronizes the biological clock with the 24-hour rhythm: The SCN is no longer free running. This time-giver (zeitgeber) signal reaches the SCN through the photosensitive retinal ganglion cells. A correct (24-hours) circadian rhythm is of great importance for human health, well-being, alertness, and performance.

Spectral Sensitivity of Photopigments

Melanopsin is the photopigment that gives the pRGC cell its intrinsic photosensitivity [2–5]. It is an opsin type of photopigment different from the rod opsin as well as different from the three types of cone opsins. All these different opsin types of pigments absorb different wavelengths. They, therefore, result in different spectral sensitivities for the different kinds of photocells.

The absorption spectra of the cones and rods are already long time known. Today, also the absorption spectrum of melanopsin has become available [6, 7]. CIE defines the spectral melanopic sensitivity based on measurements of the absorption spectrum of the photopigment melanopsin in its international standard 026:2018 [7]. It determines the intrinsic sensitivity of the pRGC cells without the interaction effect of rods and cones through neural wiring. Figure 1 shows the melanopic spectral sensitivity curve of CIE standard 026:2018 (full drawn, light blue curve). The maximum melanopic sensitivity is reached at a wavelength of approximately 480 nm. Figure 1 also shows the sensitivity curves for the S, M, and L cones and rods, based on their specific photopigments (dashed curves).

With these curves, it is possible to calculate for a specific lamp spectrum and a given amount of light on the outer surface of the eye, the spectrally weighted irradiance for the five human photopigments. Irradiance is the power of radiation received by a surface divided by the area of that surface. It is expressed in Watt/m^2 . The symbol for irradiance, E_e , is written with the subscript “e” to avoid confusion with the symbol E used for the photometric unit illuminance (i.e., $V(\lambda)$ weighted irradiance expressed in lux).

The spectrally weighted irradiance, for the example of melanopsin, is obtained from the formula:

$$E_{e, \text{ mel}} = \int E_e(\lambda) S_{\text{mel}}(\lambda) d(\lambda)$$

where

$E_{e, \text{ mel}}$ = melanopsin weighted irradiance in W/m^2

$E_e(\lambda)$ = irradiance for wavelength λ in W/m^2 (available from the lamp spectrum)

$S_{\text{mel}}(\lambda)$ = relative melanopsin sensitivity for wavelength λ , where $S_{\text{mel}}(\lambda)$ is normalized to the value of 1 at its peak

The collective name for the five spectral-weighted irradiances is “ α -opic irradiance.” Each of the five individual α -opic irradiances is named

M

Melanopic Equivalent Daylight Illuminance, Fig. 1 Relative spectral sensitivity curve for the intrinsic photosensitivity of pRGCs for light at the outer surface of the eye (light blue drawn melanopic curve) together with

the curves of rods, S, M, and L cones. Basis: 32-year, 10° standard observer. Bottom figure in logarithmic units. Source: [7]

after its photopigment name, melanopic (pRGC), rhodopic (rod), cyanopic (S cone), chloropic (M cone), and erythropic (L cone) irradiances, as

indicated in Table 1. Often the cone irradiances are simply referred to as S, M, and L cone irradiances.

Melanopic Equivalent Daylight Illuminance, Table 1 Names of the five types of α -opic irradiances and the photopigments after which they are named [8]

Photoreceptor	Photopigment	α -opic irradiance	Symbol	Unit
pRGC	Melanopsin	Melanopic irradiance	Ee, mel	W/m ²
Rod	Rhodopsin	Rhodopic irradiance	Ee, rod	W/m ²
S cone	Photopsin cyanolabe	Cyanopic irradiance	Ee, sc	W/m ²
M cone	Photopsin chlorolabe	Chloropic irradiance	Ee, mc	W/m ²
L cone	Photopsin erythrolabe	Erythropic irradiance	Ee, lc	W/m ²

Figure 2 gives for some typical lamp types the calculated α -opic irradiances for the five photoreceptors, for the condition 1000 lux at the outer surface of the eye. The values are calculated based on the formula given above for the example of melanopic irradiance. For the condition of 1000 lux at the outer surface of the eye the general formula is:

$$E_{e,\alpha} \text{ per } 1000 \text{ lux} = \frac{\int E_e(\lambda) S_\alpha(\lambda) d(\lambda) * 1000 / 683}{\int E_e(\lambda) V(\lambda) d(\lambda)}$$

where

$E_{e,\alpha}$ = α -opic weighted irradiance in W/m²; α to be specified as melanopic, rhodopic, S-cone-, M-cone-, or L-cone-opic

$E_e(\lambda)$ = irradiance for wavelength λ in W/m² (available from the lamp spectrum)

$S_\alpha(\lambda)$ = relative α -opic sensitivity for wavelength λ , where $S_\alpha(\lambda)$ is normalized to the value of 1 at its peak (given in Fig. 1)

$V(\lambda)$ = standardized relative spectral sensitivity curves for photopic vision normalized to the value of 1 at its peak

Melanopic Equivalent Daylight Ratio

The five “irradiances per 1000 lux” give a good insight into the effectiveness of a lamp in evoking a reaction in each of the five photoreceptors. For nonvisual biological lighting applications, it may often be interesting to compare the melanopic irradiance of a particular light source with the melanopic irradiance by daylight (of the same lighting level at the eye). For this purpose, Fig. 1

also gives, for each lamp type, the “melanopic equivalent daylight ratio DLeq.” It is the ratio of the melanopic irradiance of the lamp to the melanopic irradiance of 6500 K daylight (CIE standard D65 sky). This ratio is also referred to as melanopic daylight (D65) efficacy ratio [7].

The first two rows of Fig. 2 give the results for white light sources, all with a color rendering Ra of at least 80. The first column shows light sources with a correlated color temperature CCT of ca. 2800 K (incandescent lamp and LED), the second column of ca. 4000 K (fluorescent and LED), and the last column of ca. 6500 K (D65 daylight and LED). When comparing differences in irradiances for the same CCT value, the largest difference occurs for the 2800 K case. Contrary to what is often, wrongly, expected, the incandescent lamp has a larger melanopic irradiance (in this example 63 μ W/cm²) than the LED lamp with a closely same CCT value (52 μ W/cm² or 17% less). The conclusion of this example is in line with other studies [9, 10]. This is of course correct, provided that the illuminance condition at the eye is the same (1000 lux in the above example). When comparing the melanopic irradiances for the different correlated color temperature ranges, it is clear that with higher CCT values, there is a clear trend for higher melanopic irradiances. Popularly phrased: a larger blue content in white light evokes a larger effect in the melanopsin photopigment.

The last row of Fig. 2 shows the results for colored, narrow-spectrum LEDs, respectively for red, green, and blue. Note that the scale of the blue LED is different: It ranges from 0–2000 μ W/cm² while for all other lamps the range is from 0–200 μ W/cm². The blue LED results in much higher irradiances for all photoreceptors. This is,

Melanopic Equivalent Daylight Illuminance, Fig. 2 Alpha-optic irradiances of different lamp types for 1000 lux at the outer surface of the eye. S (S cone) is cyanopic irradiance, Mel (melanopsin) is melanopic irradiance, Rod is rhodopic irradiance, M (M cone) is

chloropic irradiance, and L (L cone) is erythropic irradiance. DL_{eq} is the melanopic equivalent daylight ratio (CIE D65). Bars for melanopic irradiances are shown somewhat broader to make them stand out

in particular, the case for melanopic and cyanopic (S cone) irradiances. The red LED provides no cyanopic and hardly any melanopic irradiance.

These largely contrasting properties of especially red and blue LEDs are important in therapeutic light applications.

Melanopic Equivalent Daylight Illuminance

The melanopic equivalent daylight ratio (D65) of a light source can also be used to express any photometric quantity (as, e.g., luminous flux, luminous intensity, luminance, or illuminance) in a daylight (D65) equivalent quantity. Examples for the 2790 K, 4030 K, and 6470 K white LED lamps of Fig. 2 could look like:

- A 2790 K LED lamp with a melanopic equivalent daylight (D65) ratio of 0.40 and a luminous flux of 500 lumen has a melanopic equivalent daylight (D65) luminous flux of $0.40 * 500 = 200$ lumen.
- A 4030 K LED lighting installation with a melanopic equivalent daylight (D65) ratio of 0.58, providing an illuminance of 600 lux, has a melanopic equivalent daylight (D65) illuminance (Emel,D65eq) of $0.58 * 600 = 348$ lux.
- A 6470 K LED lighting installation with a melanopic equivalent daylight (D65) ratio of 1.01, providing an illuminance of 600 lux, has a melanopic equivalent daylight (D65) illuminance of $1.01 * 600 = 606$ lux.

[Brightness perception based on physiology; Contribution of melanopsin-containing retinal ganglion cell to brightness perception; Brightness perception associated with photoreceptors' stimulations](#)

Definition

The contribution of melanopsin to brightness perception in humans is the role of photopigment melanopsin or of melanopsin-containing retinal

ganglion cell in brightness perception. Based on photometry, it is assumed that rods and cones are the only photoreceptors responsible for brightness perception. However, investigation of brightness perception should be reassessed based on stimulations of all photoreceptor classes including rods, cones, and melanopsin-containing retinal ganglion cells.

Overview

The discovery of melanopsin-containing retinal ganglion cells has led to a fundamental reassessment of visual and nonvisual processes responsible for encoding ambient illuminance. This entry provides a brief introduction of the functional role driven by melanopsin-containing retinal ganglion cells in brightness perception. It also discusses the practical difficulties involved in investigating this subject and outlines potential avenues for future research, which would benefit scientists and engineers who wish to study this topic.

Discovery of Melanopsin-Containing Retinal Ganglion Cells

Humans do not perceive light, but rather see objects by reflection. Light is characterized as a medium that conveys basic visual attributes such as color and luminance from the environment to our eye. The discovery of melanopsin-containing retinal ganglion cells (hereafter, “melanopsin cells”) has led to a fundamental reassessment of nonimage forming visual processing, such as circadian photo-entrainment and the pupillary light reflex [1]. This suggests that melanopsin cells play an important role in encoding ambient illuminance [1, 2]. Signals from melanopsin cells, stimulated by environmental light, contribute to nonimage forming processing along with signals from the classical photoreceptors viz. rods and cones.

Growing evidence indicates that melanopsin cells contribute not only to nonimage forming processing, but also to visual perception [2, 3]. For example, mice lacking classical photoreceptors but having melanopsin cells as the only

functional photoreceptor can discriminate grating patterns. Similarly, a blind person lacking functional classical photoreceptors can detect a light step. The apparent brightness is enhanced as stimulation of melanopsin increases in humans [3–5]. Although these results support the fact that melanopsin cells play an important role in the conventional visual pathway in humans, their functional role remains unclear.

Difficulties in Estimating the Contribution of Melanopsin to Brightness Perception

In humans, it is difficult to investigate whether melanopsin cells contribute to visual attributes. This limitation stems primarily from the challenges in selectively stimulating melanopsin cells while avoiding other photoreceptors and post-receptor mechanisms. For example, when brightness is measured as a function of the level of light source emission its perception can be explained by consolidated increases in stimulation of the classical photoreceptors and melanopsin cells. Although it is possible to use a monochromatic light stimulus with an approximate wavelength of 480 nm to selectively stimulate melanopsin cells, the classical photoreceptors would also be strongly stimulated, inducing luminance and color perception.

Here, therefore, to stimulate melanopsin independently of other photoreceptors particular light stimuli known as metamers were used. Metamers have the same color and luminance but have distinct spectral power distribution. These stimuli can independently stimulate melanopsin while keeping other photoreceptors silent, ensuring that the color and luminance of these stimuli do not change. The way of stimulation is well-known as silent-substitution paradigm in psychophysics [6].

Melanopsin and Human Brightness Perception

The term “brightness” is used to denote the perceived apparent intensity of ambient light and is

different from the photometric term “luminance.” Luminance is estimated from luminous efficiency functions, that is, a linear combination of the L- and M-cone spectral sensitivities measured by heterochromatic flicker photometry at high temporal frequency, without considering any input from the S-cones and melanopsin cells. Brightness does not correlate with photometric luminance based on the assumptions of the conventional rod/cone visual pathway [7]. Furthermore, brightness does not require spatial information [8] and increases with correlated color temperature even for isoluminant stimuli [9]. Here, a brightness-matching experiment for assessing melanopsin contribution to brightness perception will be introduced.

Brightness-Matching Experiment

A test stimulus and reference stimulus were sequentially presented to subjects, separated by audible tones. The reference stimulus was presented after the test stimulus and vice versa. The background transitioned over 2 s to the first stimulus, which was presented for 1 s. Then, the first stimulus transitioned over 2 s to the second stimulus, which was presented for 1 s. Finally, the second stimulus reverted over 2 s to the background. This was done to minimize the effect of abrupt changes in stimulus. The observers had to choose between the first and second stimulus

presentation with regard to brightness. Luminance of the nine different light flux stimuli varied between -40% and $+50\%$ relative to the background.

The test stimulus subtended 95° of the visual angle. Observers were seated 4.5 cm in front of the diffuser. Each session lasted approximately 40 min, including an initial adaptation of 5 min, during which time observers were instructed to keep their right eye open, especially when the integrating sphere provided test and reference stimuli for 10-s periods. The left eye was masked throughout the test. Data were averaged from three or five sessions.

In the experiment, brightness was matched between the melanopsin stimulus and the light flux stimulus by adjusting the luminance of the light flux stimulus. A two-interval alternative forced-choice procedure with the method of constant stimuli was used to identify a light flux stimulus with brightness matched to the melanopsin stimulus. Three melanopsin stimuli (-11% , 0% , and $+11\%$) were used as test stimuli. Because only melanopsin stimulation of the test stimulus varied from the background, the apparent brightness could therefore be attributed to the difference in stimulation of melanopsin.

The brightness of the melanopsin stimulus was compared with the light flux stimuli (Fig. 1). The

Melanopsin Contributions to Human Brightness Perception, Fig. 1 Brightness matching. Percentage of responses when the observer perceived that the light flux

stimulus was brighter than the melanopsin stimulus. Psychometric functions were fitted to the data from the logistic function

curve represents a logistic function, and a horizontal shift of the curve from zero represents the amount of apparent brightness induced. Results show that the curve shifted to the right as melanopsin stimulation increased, indicating that the observers perceived increased brightness.

When the shift was compared among conditions, it was consistently observed that shifts for +11% melanopsin stimulation were significantly larger than those for -11% and 0% melanopsin stimulation in all observers. Moreover, the shifts for -11% melanopsin stimulation were significantly smaller than those for 0% melanopsin stimulation in all observers (Fig. 2, open symbols). These results indicate that all observers perceived progressively more brightness as melanopsin stimulation increased.

Flicker-Photometry Experiment

Individual variations in luminous efficiency function among observers were examined. The luminance of the melanopsin stimulus was measured by flicker photometry with the method of adjustment in all observers (Fig. 2, solid symbols). The relative change in luminance for five melanopsin

stimuli ranged from -0.5% to 2.4%, with an average of 1.2%. No significant difference in the slope of the linear regression line was found for luminance by flicker photometry. These results show that the luminance variation for observers was negligible; this indicates that the melanopsin did not contribute to luminance perception.

Spectral Sensitivity Curve for Melanopsin Photoreception

Test stimuli were represented in a receptor-stimulation space that used stimulations of three types of cones and melanopsin. The receptor-stimulation space is a natural extension of cone-stimulation space (also called cone-excitation space). Because light stimulation correlates with the cell's stimulation, not with the cell's activity a term "stimulation" is used here. Cone-stimulation space uses three fundamentals, corresponding to the stimulation of the three kinds of retinal cones. The fundamentals were so designed that the total amount of stimulation of L and M cones was equivalent to the photopic luminous efficacy

M

Melanopsin Contributions to Human Brightness Perception, Fig. 2 Relative change in brightness (open symbols) and in luminance (solid symbols) for all observers. The shifts for the +11% melanopsin stimulation condition

were significantly greater than those for the -11% and 0% conditions while the shifts for the -11% condition were significantly smaller than those for the 0% condition

function $V(\lambda)$. In addition to these fundamentals, a spectral sensitivity curve for melanopsin was used. These were mapped onto four orthogonal axes in receptor-stimulation space.

The spectral sensitivity of photopigment melanopsin at cornea was estimated using a pigment template nomogram, a standard shape of visual pigment absorption coefficient, $S(\lambda)$ [10], with a peak wavelength ($\lambda_{\max}$) of 480 nm. The lens and macular pigment density spectra, $L(\lambda)$ and $M(\lambda)$, in the peripheral visual field were those used by Stockman et al. [11]. The fraction of incident light absorbed by the receptor depends on the peak axial optical density (D_{peak}). As there was no prior reference, D_{peak} was kept as 0.1. Hence, the spectral sensitivity curve for melanopsin photoreception, $\text{Mel}(\lambda)$, was calculated based on light absorption by the lens and macular pigment and photopigment peak axial optical density [12, 11].

$$\text{Mel}(\lambda) = A(\lambda) \left(1 - 10^{-D_{\text{peak}} \cdot S(\lambda)} \right)$$

where

$$A(\lambda) = 10^{-(L(\lambda) + M(\lambda))}$$

Although short-wavelength sensitive cones (S-cones) and melanopsin photoreception do not affect the photopic luminance efficiency function (i.e., luminance), photopic luminance units (cd m^{-2}) were used. Similar to S-cone stimulation [13], the melanopsin stimulation was defined as the amount of stimulation produced by an equal energy spectrum of luminance 1.0 cd m^{-2} . The resultant spectral sensitivity function of melanopsin in melanopsin cell in the peripheral visual field displayed a peak of 872.1 (i.e., K_m) at a peak wavelength of 493 nm. The shape of this spectral sensitivity curve was similar to that proposed by Lucas et al. [14]. Tsujimura et al. further considered the human macular pigment density at 10-deg for the estimation [15]. Although the shapes of spectral sensitivity curves are slightly different from that proposed by Lucas et al., the photoreceptor stimulations

calculated from the primaries were in agreement with the experiment.

Test Stimuli in Silent-Substitution Paradigm for Independent Stimulation of Melanopsin

To stimulate melanopsin independently of other photoreceptors the silent-substitution paradigm was used [6]. A four-primary illumination system was used to investigate melanopsin-cone interactions [2]. Two test stimuli were presented: (i) melanopsin stimulus with varying melanopsin stimulation while keeping stimulation of the three types of cones constant (Fig. 3), and (ii) light flux stimulus with varying radiant flux of the stimuli with constant spectral composition which reduced/increased the radiant flux uniformly at all wavelengths. (See published literature for detailed description of the system [3, 15].)

Test stimuli were represented in a receptor-stimulation space that uses stimulations of three types of cones and melanopsin [15]. The background stimulus had a CIE coordinate of (0.351, 0.311) and a luminance of 356 cd m^{-2} . The receptor stimulations for the background were 255 cd m^{-2} , 102 cd m^{-2} , and 379 cd m^{-2} for the L-, M-, and S-cone, respectively, and 1159 cd m^{-2} for melanopsin. The ratio of L- to M-cone stimulation was 2.5, identical to that for 570 nm monochromatic light. For a 570 nm yellow background, the red-green ratio in flicker detection was almost constant with respect to changes in mean luminance. Retinal illuminance in response to the background was 2.8 log photopic troland and 3.2 scotopic troland with a pupil size of 1.5 mm to minimize the involvement of rods. The retinal irradiance in the photon flux of the control stimulus was $15.1 \text{ log photons cm}^{-2} \text{ s}^{-1}$.

In general, the silent-substitution paradigm is a sophisticated technique to investigate the function of melanopsin photoreceptors. However, it must be noted that one of limitations of the silent substitution is that the change in stimulation (i.e., contrast) of target photoreceptor is small. The change in independent stimulation of melanopsin

Melanopsin Contributions to Human Brightness Perception, Fig. 3 Experimental setup. The apparatus consists of an integrating sphere controlled by microcomputer (left), and the spectra used for high- and low-melanopsin stimuli (right)

strongly depends on the choice of primaries of light source and importantly the change is usually not so large. This limitation makes it difficult to investigate a function associated with melanopsin stimulation. Furthermore, because the silent-substitution paradigm is based on spectral

sensitivity curves of photoreceptors results are sometimes contaminated from the nontarget photoreceptors. In addition, spectral sensitivity curves vary among individuals according to optical properties at retina. Therefore, the experiment must be conducted carefully.

Melanopsin Contributions to Human Brightness Perception, Fig. 4 Relative changes in brightness with and without artificial pupil

Brightness-Matching Experiment with Artificial Pupil

As melanopsin cells contribute greatly to the pupillary pathway, results of the brightness-matching experiment may be influenced by pupil size. Therefore, to control for the pupil size the above experiment using an artificial pupil of 1.5 mm diameter was repeated. Results were similar to those of the previous experiment (Fig. 4), indicating that the influence of variation in pupil size was negligible.

Luminance, Color, Brightness, and Melanopsin in Photometry

In photometry, the apparent brightness of a light source does not correlate significantly with its luminance, especially when a chromatic stimulus is used. Therefore, it was assumed that color signals contribute to brightness. For example, a stimulus appears brighter as chromatic saturation increases (sometimes referred to as the Helmholtz–Kohlrausch effect), which explains the contribution of color to brightness.

Brightness is independent of photometric luminance based on the assumption of the

conventional rod/cone visual pathway [7]. Furthermore, brightness perception does not require spatial information [8] and increases with color temperature, even for isoluminant stimuli [9]. Because previous studies did not consider melanopsin cells, it is likely that a part of these phenomena can be explained by a melanopsin contribution to brightness perception.

Natural light has complex spectra and the spectral sensitivity curves of the photoreceptors overlap. Therefore, the natural light usually stimulates all photoreceptor classes. To evaluate brightness perception for natural light based on physiological substrate, it is important to estimate the weights of combination of the photoreceptors. To achieve this, color matching functions based on all photoreceptor classes including melanopsin photoreceptors might be required. Further research on the integration process of melanopsin and the other photoreceptors will hopefully provide an answer to this question in photometry.

Melanopsin Retinal Ganglion Cells

Robert Lucas

Faculty of Biology Medicine and Health,
University of Manchester, Manchester, UK

Synonyms

Intrinsically photosensitive retinal ganglion cells; ipRGCs; mRGCs; Photosensitive retinal ganglion cells; pRGCs

Definition

A subset of retinal ganglion cells are characterized by their expression of melanopsin and their ability to respond directly to light. Melanopsin is an opsin protein structurally and phylogenetically related to rod and cone opsins. It binds retinaldehyde as a chromophore and activates a G-protein signaling cascade upon photon absorption. As a result, melanopsin retinal ganglion cells are depolarized by light even when physically, pharmacologically, or genetically isolated from rod and cone influences. This allows them to function as an independent origin of visual information. mRGCs are known to encode environmental brightness for such visual reflexes as circadian photoentrainment and regulating pupil size. They likely also make as yet incompletely defined contributions to other visual processes including perceptual vision.

Discovery and Functions

Until around the turn of the millennium it was considered self-evident that all aspects of human vision could be ultimately attributed to the activity of rod and/or cone photoreceptors. With hindsight, it is possible to find isolated examples of findings in several branches of vision science that questioned this assumption, but the concerted effort that led to the discovery of a third photoreceptor type came from researchers interested

in a particular visual function – circadian entrainment [1].

Like almost all life on earth, humans have an internal circadian clock that oscillates with a period close to 24 h. In order to fulfill its function of coordinating physiology and behavior to the varying demands of the astronomical day, this clock needs to be accurately set (or “entrained”) to local time. Entrainment relies upon a representation of the light:dark cycle provided by a dedicated retinal projection to the hypothalamic site of the circadian oscillator, the suprachiasmatic nuclei (or SCN). Studies of human subjects and rodent models of retinal dystrophy revealing that circadian entrainment was buffered against massive loss of rods and cones culminated in the demonstration that this function was retained even when these conventional photoreceptors were completely absent [2]. An explanation for this finding was provided by the discovery that the retinal ganglion cells projecting to the SCN are in fact directly photoreceptive [3].

Melanopsin is one of a number of opsin proteins known to be expressed outside of the eyes in nonmammalian vertebrates. It was initially discovered in the photosensitive dermal melanophores of *Xenopus laevis* [4]. Orthologues were subsequently identified in mammalian genomes and found to be expressed in the retinal ganglion cells innervating the SCN. These ganglion cells were shown to lack their intrinsic photosensitivity in mice lacking melanopsin [5], while inclusion of melanopsin was shown to be sufficient to induce photosensitivity in a variety of non-light-responsive cell types [6–8].

Although initially discovered in the search to understand circadian entrainment, melanopsin retinal ganglion cells are now thought to contribute to a wide variety of visual responses [9]. mRGCs project not just to the SCN but also to other parts of the hypothalamus, the pretectum, the superior colliculus, the visual thalamus, and the nucleus of the optic tract [10, 11]. Their established functions extend to providing the pupil light reflex, regulating sleep/alertness, and suppressing pineal melatonin production. There is also evidence that they regulate mood and retinal development and

influence retinal physiology by signaling to other cells in the retina.

At present, the nature and extent of mRGC contributions to perceptual vision is unclear. The appearance of mRGC fibers in projections to the dorsal lateral geniculate nucleus and established functional connections to other cell types in the retina via synaptic and gap junction connections raise the possibility that mRGCs could have both direct and modulatory influences on perceptual vision. Evidence from both mice and primates supports the view that melanopsin can both provide an origin for aspects of visual light adaptation and itself support visual discrimination [12–15]. In primates, at least some ipRGCs receive antagonistic input from short- and long/medium-wavelength cones and may contribute to blue:yellow discrimination [16].

Anatomy and Physiology

The defining feature of mRGCs is their expression of melanopsin, and consequent intrinsic photosensitivity. In rodents, at least six morphologically distinct classes of retinal ganglion cell (termed M1 to 6) meet this criterion [17]. The best characterized of these is the M1 class, which has the highest melanopsin expression (and the most prominent intrinsic light response) and is responsible for both circadian entrainment and the pupil light reflex. Other classes differ in their central projections, the nature and spatial extent of dendritic arborization, and their degree of melanopsin expression [17]. Morphological diversity is also a characteristic of the mRGC population in primates and humans, although fewer subtypes have so far been identified in primate than rodents [16, 18].

The dendrites of mRGCs are sites of melanopsin-driven phototransduction but also of synaptic inputs from bipolar and amacrine cells. As a result, in the intact retina, the spike-firing pattern of mRGCs is defined in part by melanopsin photoreception and in part by synaptic influences originating in signals from rods and cones. As mRGCs lack the membranous disks used by rods and cones to maximize

photopigment concentration, they have very poor photon capture efficiency. As a result, melanopsin has an appreciable impact on mRGC firing only at rather high light intensities (several decades above the threshold for cone activation). Even at these light levels, the rate of melanopsin photoisomerization is low and its phototransduction cascade has to have high gain [19]. This is achieved by having a long activation time, with the consequence that the melanopsin light response has poor temporal resolution. Under some circumstances, this phenomenon can be extreme with light-induced firing of mRGCs and melanopsin-driven pupil constriction lasting several tens of seconds after the light has been turned off. Under more natural conditions, these sensory characteristics imply that melanopsin provides a low spatiotemporal resolution signal of environmental brightness, with mRGCs relying upon input from rods and cones to encode lower light levels and to track higher frequency changes in light intensity [20].

Melanopsin, like all animal opsins, is a member of the G-protein coupled receptor superfamily of proteins. The molecular identity of the critical elements of its phototransduction cascade is unknown. Melanopsin can signal via a G-protein of the Gq/11 class, which links opsin activation to membrane depolarization via phospholipase C and TRP channels [21]. However, melanopsin also likely interacts with other signaling cascades in at least some mRGCs [22, 23].

Spectral Sensitivity

Measuring the spectral absorbance properties of melanopsin directly has proved challenging. It is not found in sufficient concentrations to allow direct *in vivo* microspectrophotometry. While it has been possible to purify melanopsin from harvested retinas and from heterologous cell-based expression systems, the quality of these preparations falls far short of that achieved with rod or cone opsins. As a result, a precise description of melanopsin's spectral absorbance in the dark state, and following light absorption, remains

elusive. Nonetheless, action spectra for melanopsin-driven activation of mRGC activation and downstream responses in a variety of mammalian species are consistent with the hypothesis that in the dark state melanopsin's spectral sensitivity can be well described by the standard opsin: vitamin A1 template peaking around 480 nm [20]. This puts it close to the spectral sensitivity of human rod opsin but far from that of the cone photoreceptors that are conventionally considered to dominate vision at moderate and high light levels. Importantly, its spectral sensitivity is also significantly short wavelength shifted compared to $V(\lambda)$ (the spectral efficiency function of photopic vision), which is used in quantifying illuminance. This implies that spectrally distinct natural and artificial light sources might have quite different effective intensity for melanopsin even when matched for illuminance [20] and has led the Committee International de l'Eclairage to establish an independent measurement standard for melanopsin-dependent light responses (CIE S 026/E:2018).

Memory Color

Christoph Witzel¹ and Karl Gegenfurtner²

¹School of Psychology, University of Southampton, Southampton, UK

²Department of Psychology, Giessen University, Giessen, Germany

Synonyms

Canonical color; Diagnostic color; Typical color

Definition

A memory color is the color a beholder considers to be characteristic for an object based on their experience with that object. For example, the memory color of a banana is yellow for most people because they associate a banana with yellow in their memory.

Conceptual Clarifications

The concept of memory color should not be confused with color memory. Color memory is a general term that describes an observer's ability to memorize a color. In contrast, a memory color is an association between a color and an object in memory (for review, see [1, 2]). The notion of memory color is strongly related to *memory color effects*, *canonical and typical colors*, and *color diagnosticity*; but a closer look reveals that there are also important differences.

Memory Color Effects

The term “memory color” is historically linked to the idea of a memory color effect (for review, see [2]). The term has been coined by Ewald Hering in 1878, who associated memory colors with the idea that knowledge about the typical colors of objects affects the perception of the actual color of the objects. However, the fact that an observer knows about typical object colors does not necessarily imply that this knowledge influences the

Memory Color, Fig. 1 What is the banana’s memory color? Panel **a** shows a red Dacca banana to illustrate the fact that a memory color, such as the yellow of a banana, depends on the observer’s familiarity with the object, e.g., with yellow Cavendish rather than red Dacca bananas. Panel **b** illustrates the color distribution that corresponds

to the photo in panel **a**. X- and Y-axes are the green-red (u^*) and blue-yellow (v^*) dimensions of CIELUV color space. The photo also varies in Lightness (L^*), the third dimension, which is not shown to avoid clutter. Photo taken from https://upload.wikimedia.org/wikipedia/ar/b/b4/Red_banana.jpg

way they see the actual object colors. For this reason, it is sensible to disentangle the concept of a memory color from the idea of a memory color effect on color appearance (as, e.g., in [3]), and hence, not all research on memory colors is about the memory color effect (for reviews, see [1, 4–6]).

Canonical and Typical Colors

The term “memory color” ultimately refers to the same phenomenon as “canonical” (e.g., in [7–9]) and “typical color” (e.g., in [5, 10]), though with different emphases and connotations. The idea of a “canonical color” suggests that there is a standard (or reference) that is shared among all observers and that unambiguously determines the association between an object and its canonical color. A typical color focuses on the color as a property of an object. Hence, the ideas of “typicality” or “prototype” refer primarily to the occurrence of object colors in the physical environment.

In contrast, the concept of memory color emphasizes the psychological, subjective nature of perception and memorization. There are two major aspects underlying the subjective nature of memory colors. First, memory colors depend on the observer’s familiarity and experience with an

object. For example, not all bananas are yellow like the most common type of Cavendish bananas. They can also be red, such as the Red Dacca banana (cf. Fig. 1a). Nevertheless, most people associate a banana with yellow, not red, because they are more familiar with yellow bananas. Second, memory colors depend on which color an observer considers to be representative. The colors of most objects correspond to complex color distributions (cf. Fig. 1b), which vary across exemplars and over time. Even the yellow Cavendish bananas can be green or brown depending on their ripeness. Although we know this, we consider the yellow color of a ripe banana to be the most representative and typical.

At the same time, the ideas of canonical and typical colors also require, at least implicitly, assumptions about a beholder (e.g., [11]). Often an experimenter determines which color is canonical or typical for an object, or a computer program computes typicality based on image statistics. In these cases, the choice of canonical or typical colors depends either on the experimenter’s prior assumptions of objects and their criteria of typicality, or on the sample of images and the criteria of typicality processed by the algorithm. The mere idea of typicality implies a

real or virtual beholder (i.e., a human being or a simulating algorithm) that integrates the single exemplars encountered hitherto into a typical representation. For this reason, the notions of canonical or typical color are largely equivalent to the one of memory color.

Color Diagnosticity

While the term “memory color” characterizes a color, color diagnosticity characterizes an object ([12], for review, see [1, 2, 6]). It describes the degree to which an object is associated to, and hence characterized by, a particular color. We may distinguish objective and subjective color diagnosticity. In the objective sense, an object is color-diagnostic when it only occurs in a limited range of colors in the environment. For example, ripe Cavendish bananas only occur in a particular range of yellowish colors that is characteristic, or diagnostic, of ripe bananas. In contrast, cars are *color-neutral* (i.e., not color-diagnostic) because they occur in arbitrary colors. As the above example of the red Dacca banana showed, the objective co-occurrences of objects and colors and the subjective knowledge about them are not a priori the same. Subjective color diagnosticity describes the degree to which a beholder associates an object with a color, depending on the beholder’s prior experiences, familiarity, and criteria of typicality. Hence, subjective color diagnosticity implies that an observer has a memory color for an object.

Measurement

The method used to measure memory colors can make an important difference. For example, the word “lemon” is strongly associated to a yellow color. In contrast, an outline shape of a lemon might not be easy to recognize and is ambiguous because it could also represent a green lime instead of a yellow lemon (cf. [13]). The measurement of memory colors depends on three major characteristics: the identification of the object, the identification of the representative color (typicality), and the strength of the association between object and color (diagnosticity).

Object Identification

In order to measure a beholder’s memory colors for an object, the beholder must be able to recognize the object. This does not only require that the beholder is familiar with the respective kind of object, but it also depends on how well the exemplar used for the measurement may be identified as the respective kind of object. In particular, many measurements of memory colors use two-dimensional images, and the question arises whether the pictorial representations are recognizable and representative. For example, outline shapes of fruits, such as oranges or carrots, are barely recognizable even though people are highly familiar with these objects (cf. [13]). As a consequence, the measurement of memory colors may be affected by particularities of the image sampling. Some image databases address this problem by providing familiarity indices for the images, such as the Snodgrass line drawings [14].

Memory colors may also be investigated by describing objects verbally (i.e., by words or expressions). In this case, it is important to consider how specific and informative the term is about an object (e.g., fruit vs. banana vs. Cavendish banana), and how well observers know the meaning of those terms, e.g., the words “aubergine,” “eggplant,” and “*Solanum melongena*” refer to the same fruit, but may differ in comprehensibility.

Color Typicality

Memory colors consist of a most typical color that is associated with the respective object and a region of tolerance, within which concrete colors may still be accepted as instances of the memory color. The typical color may be represented by the average of all occurring colors, by the color that occurs in most cases (mode), by the color that is “purest” (i.e., maximally saturated), or simply by a whole region of colors (exemplar-based typicality).

In order to assess the range and typicality of colors associated with the objects, color adjustment or rating techniques may be used. In the former, observers adjust the color of the objects to the typical color, and the distribution of these adjustments informs about the nature and the

precision of the typical color (e.g., [3]). In rating tasks, observers evaluate how well a particular color matches the typical color of an object [15].

Color Diagnosticity

It is important to note that there may be an asymmetry in color-object associations: an object may refer to a specific color, even though the color might barely evoke the object. For example, while blue is highly diagnostic of a smurf [13], the first thing that comes to one's mind when thinking about blue is the sky or the sea rather than a smurf. The measurement of color diagnosticity and memory colors concerns the first case that is the strength, with which an object refers to a color.

A distinction may be made between conceptual and perceptual measures of color diagnosticity. A typical conceptual measure involves verbal elicitation. Observers are asked to name the most important object features, and color diagnosticity is assessed by the priority, with which color is named among these features. Other techniques require observers to rate how important color is to describe the object (reviewed, e.g., in [5]).

A perceptual approach consists in showing the respective objects (mostly their images) without color and asking the observer to indicate their typical color [13]. The accuracy and speed of the answer give insight into the strength of the object-color association. In particular, the speed may also reflect the automaticity of the memory color knowledge. Moreover, this technique also ascertains the validity of the measures for the particular stimuli. This, however, is also the drawback of this technique, since measurements cannot directly be generalized to other representations of the respective objects.

Characteristics of Memory Colors

Object and Scene Recognition

There is ample evidence that memory colors promote object and scene recognition. In particular, color-diagnostic objects and scenes are identified more easily when seen in their typical colors (for a review see [1, 5]). At the same time, chromatic

heterogeneity (cf. Fig. 1b) and three-dimensional shape cues increase the accuracy and precision of memory color measurements [11]. These observations suggest that memory colors and other visual characteristics of objects and scenes are tightly bound together and interact with each other.

Priming Effects

Furthermore, color-diagnostic objects automatically elicit the idea of the respective memory color and vice versa. In particular, so-called object-Stroop tasks have shown that colors are identified more rapidly when seen on the respective color-diagnostic object. In turn, priming paradigms revealed that colors facilitate the identification of the labels for color-diagnostic objects. Mentioning color-diagnostic objects verbally directs gaze automatically toward their memory colors. Similar to cueing, this implies an orientation of overt attention toward memory colors (for review, see [2]).

Color Constancy

It has been suggested that memory colors might help to establish color constancy, the ability to recognize surfaces across illuminations. The effect of the illumination color on the overall color of a scene might be estimated by comparing the actual color of a color-diagnostic object with its expected memory color. However, investigations of this idea only found very small effects of memory colors on color constancy, if any (for review, see [1, 2]).

Development

Interference effects that reveal memory color knowledge have been found at the age of 3.5 years with an object-Stroop-paradigm [9], and for 2- to 3-year-old children in a free-looking paradigm (e.g., [10]). A study using a preferential-looking procedure even found some evidence that infants possess memory colors as early as 6 months [8]. Nevertheless, preschool children (up to 5 years) may still have difficulties, when they are asked to identify the appropriate color for very common color-diagnostic objects (e.g., [7]).

The Memory Color Effect

According to the classical idea of a “memory color effect,” memory colors influence the appearance of the actual color of objects. The familiarity with the object-color association implies an expectation about the color of a concrete exemplar of an object, and this expectation contributes to the perception of its actual color. In this way, memory color effects indicate that color appearance depends on the object, on which the color is shown, as well as on the experience and the prior knowledge of the observer. For example, an observer may know that bananas are yellow. Does this knowledge influence how this observer sees the actual color of a banana?

Evidence

During the twentieth century, several studies pursued Hering’s original idea that memory colors affect the perception of the objects’ actual colors. Results of those studies were mixed, and it often remained ambiguous whether memory colors really affect perception rather than biasing memory retrieval and judgment (for review, see [2, 13]).

An achromatic adjustment approach was developed to assess genuine effects on color appearance [3]. If a color-diagnostic object automatically elicits the impression of its typical color, a banana should still appear to be yellow even if it is completely grey. To test this, participants were asked to adjust the colors of color-diagnostic

objects so that they look grey to them. If the object alone induces the impression of its typical color then the observers have to counteract this impression in order to see the object so that it looks subjectively grey to them. And indeed, the participants of those studies shifted the color adjustment toward the color opposite to the typical color. For example, they adjusted the banana slightly toward blue because blue is the color opponent to yellow. They did this, even though they had only to match the color of the object to the color of the grey background. This implies that they really saw the banana as yellow or at least slightly yellowish when it was actually grey. Figure 2 illustrates the idea and the rough size of the effect with a simple display taken from a follow-up study [16].

Determinants

Meanwhile, several studies have reproduced memory color effects using different methods and techniques. Besides achromatic adjustments, tasks included pairwise comparisons (as in Fig. 2), hue scaling, categorization, and the assessment of afterimages. Memory colors have been shown for natural objects, such as fruits and vegetables (e.g., [3]), for human-made objects, such as a Smurf and a German mailbox (e.g., [13]), and for scenes. At the same time, it also became clear that these memory color effects do not alter the ability to see color differences in discrimination tasks. Instead, they seem to affect how visible color information is subjectively experienced, maybe

Memory Color, Fig. 2 Memory color effect. The banana A is completely greyscale, while the banana B is slightly bluish. Most observers perceive A as yellowish and B as grey (from [16]). Note that the image is calibrated for an

sRGB monitor and may vary in color across display devices. On an sRGB monitor the difference between A and B approximates the memory color effect measured with the achromatic adjustment task [3]

similar to how attention modulates sensory information before it enters visual experience (for review, see [1, 2]).

Follow-up studies also allowed specifying factors that modulate memory color effects. Images with less perceptual information, such as outline shapes, yield weaker memory color effects. It has also been shown that memory color effects are strongest for objects with yellowish or bluish colors along the daylight locus, along which observers are least certain about their color appreciation. Red stimuli seem not to yield any memory color effects. These observations explain why some of the classical studies that used outline shapes and/or red objects yielded inconsistent findings (e.g., [13]; for review, see [1, 2]). How those determinants modulate the size memory color effects across stimuli might be understood through a Bayesian approach to the interaction between expectations and perception. A simple Bayesian model partially accounts for the variation of memory color effects [17]. Finally, a recent study found paradoxical memory color effects for faces under very particular viewing conditions: Faces look greenish when seen in the monochromatic yellow light of a (low pressure) sodium vapor lamp [18].

Neural Substrate

Neuropsychological studies found that brain injuries can affect object color knowledge (memory colors) independently from shape knowledge, color perception, and color naming, and that conceptual object color knowledge (“Bananas are yellow”) is independent from the ability to perceptually recognize whether an object is in its typical color (for review, see [4, 6, 23]). It has been suggested that perceptual information about memory colors are processed in an “anterior color center,” i.e., a parahippocampal, medial area of the cortex [4]. A recent single case study showed that a patient with color-specific deficits was able to verbally recall memory colors of objects and to recognize whether an object is shown in its typical color; but he was unable to judge whether a color patch corresponds to the memory color of an

object when the object is presented as a grayscale image separate from the color patch [19]. In-line with the aforementioned behavioral evidence, this observation suggests that memory colors are neurally represented as holistic templates (or “Gestalts”) that integrate perceptual color information with other visual information of the objects. Research into the neural basis of memory color effects indicates that greyscale images as well as verbal descriptions of color-diagnostic objects elicit color-specific activity in the primary visual cortex (V1) and the human visual area 4 (hV4) [20–22]. Taken together, these observations allow for the speculation that the perceptual memory color templates in the anterior color center modulate color experience through feedback connections to earlier visual areas. Nevertheless, the areas and their connections are still under research.

Definition

The Mesoamerican Color Survey (MCS) collected color-naming and categorization data from approximately 900 speakers from each of 116 indigenous languages from regions in Mesoamerica or Central America. Analyses of these data were originally reported by Dr. Robert E. MacLaury, principal investigator of the survey. The MCS data exist as a public-access color categorization and naming digital archive, in conjunction with other color categorization data

collected by MacLaury, and are available at <http://colcat.calit2.uci.edu/>.

Introduction

Human categorization behavior is widely studied across the behavioral sciences. It underlies many cognitive functions, including concept formation, decision making, learning, and communication. Color appearance, similar to other natural categorization domains, has distinctive features or properties that vary along continuous dimensions. Semantic color categories, their formation, their best exemplars and boundaries, and the influence of these on human behavior have been the topics of much empirical study, receiving considerable attention from anthropologist, linguists, cognitive scientists, and psychologists. The general aim of such research is to understand human color categorization and how it is cognitively and culturally represented across languages. For the case of color categories, the literature suggests that there are “universal trends” in human color representations with the category best exemplars being predictable across languages [1–7], and there are culturally specific color categorization influences [8–15], as well as human evidence [16–22] and simulated color category evolution evidence [23–27], suggesting combinations of universal, cultural, and pragmatic influences on color categorization and naming behaviors.

The Mesoamerican Color Survey (MCS) is one of the two existing databases (the other being the World Color Survey or WCS; see ► “World Color Survey”) which directly investigated, on a large scale, color naming and categorization across many linguistic societies. The MCS and the WCS employ nearly identical standardized procedures for evaluating large numbers of color stimuli, languages, and informants. The Mesoamerican Color Survey was conducted by Robert E. MacLaury during the years 1978–1981. MCS data were collected by MacLaury himself, or by research associates and colleagues in Mesoamerica, whom MacLaury trained and directed. The MCS data represent interviews with 900 speakers

of some 116 Mesoamerican languages. It is estimated that more than 100 indigenous languages are spoken in Mexico and Central America. Like most languages each MCS language has a color lexicon that partitions environmental color appearance stimuli according to a pattern that is specifically relevant to a given language’s speakers. But every local MCS system of color categorization also shares characteristics with systems observed for other Mesoamerican languages and with those of languages elsewhere in the world. MacLaury published analyses of the MCS data in the context of his *Vantage Theory* modeling approach ([28–30], see ► “Vantage Theory of Color”).

MCS and Theories of Color Categorization

Humans can discriminate on the order of 10^6 different colors, many more colors than any individual can name reliably. Most of the 7000 living languages have some form of a color lexicon. Various theories in the literature have sought to account for empirical findings on how each language represents color concepts and how such representations evolve, changing over time, and successively form hierarchical linguistic representations of color appearance similarity. In 1969 Brent Berlin and Paul Kay were among the first to systematically empirically examine how different linguistic societies represented color and theorize how color lexicons might similarly evolve ([1], see ► “Berlin and Kay Theory”). In the data they collected from 20 unrelated language families, they found (a) that there exist universal cross-linguistic constraints on color naming and (b) that basic color terminology systems tend to develop in a partially fixed order.

Berlin and Kay made two conjectures about the evolution of color lexicons: (1) There is a limited set of basic color terms (abbreviated as BCTs) in most languages, which are distinct from other color terms that an individual might use to name colors. (2) Color lexicons evolve from simple to complex, along highly constrained paths, starting

from two BCTs corresponding to warm-or-light and dark-or-cool categories in the most reduced lexicons and extending to 11 BCTs as seen in English and other languages spoken in industrialized societies. The Berlin and Kay theory is the basis for a mainstream approach to color categorization theory, along with its subsequent formulations using the World Color Survey (WCS) data ([2–4, 7], see ► [“World Color Survey”](#)).

While much empirical support exists for the Berlin and Kay/WCS theoretical approach, alternative explanations have also been suggested. Researchers directly involved in the WCS project, who collaborated with Berlin and Kay, have suggested that some linguistic societies might follow alternative patterns of color lexicalization, suggesting possible deviations from a hue-based model of color category universality that was central to the Berlin and Kay and WCS research program. The suggestions raised, for example, questioned whether a universal BCTs conjecture positing “a total universal inventory of exactly 11 basic color categories exists from which the 11 or fewer basic color terms of any language are always drawn” ([1], p. 2) was the best model to describe the extensive amount of data accumulated by the Berlin and Kay and WCS efforts. Robert E. MacLaury was among those who sought to explore alternative explanations, which was the impetus for his direction of the MCS project [11, 28–30]. In the 1970s MacLaury was an anthropologist working with Brent Berlin and Paul Kay, conducting fieldwork in Oaxaca, Mexico, and later working on the World Color Survey, and the Mesoamerican Color Survey was the basis for his PhD dissertation obtained from the University of California, Berkeley in 1986. In 1997 MacLaury successfully used the MCS data as the basis for an alternative color-naming and categorization theory, called Vantage Theory [28]. That approach presents a model of color categorization at the lexeme level where color categories are constructed as vantages (see ► [“Vantage Theory of Color”](#)). In the context of this approach, MacLaury’s book provides an extensive inventory of the organization and semantics of color categorization in Mesoamerica.

The MCS: History, Methodology, and Data

Historical Background

As noted earlier, the Mesoamerican Color Survey (MCS) includes 116 surveyed societies, each with a different Mesoamerican language or dialect, assessing approximately 900 native-language speakers from indigenous populations in Mesoamerica. The MCS employed color stimuli from the WCS stimulus palette shown elsewhere in this volume (see ► [“World Color Survey”](#)). Figure 1 above visually illustrates how the MCS substantially extends the geography of areas surveyed and thus extends beyond the wealth of information provided by the widely cited and valued WCS. It does so by replicating an estimated 20 languages found in the WCS, providing observations for 96 additional languages using the WCS’ standardized data collection procedures. Such an extensive survey of indigenous languages is likely no longer possible in 2015, due to dramatic increases in exposure over the last 25 years of native-language monolingual speakers to English-language broadcast media and entertainment.

The original MCS data was handwritten on paper, and while MacLaury published analysis and theory of MCS data (notably, [28]), thousands of pages of raw MCS data have never been publicly available and have not been subjected to the kinds of highly informative methodological approaches that have more recently been used to reveal the insights learned from the WCS data (e.g., [3–6, 20, 21, 31, 32]). MacLaury focused on MCS language groups across Northwest Mesoamerica for a particular reason: to investigate what he conceived as an alternative theory of color category systems that emphasized “brightness”-based categories in naming – as an alternative to historically prominent theories emphasizing hue-based categories in naming – and to test hypotheses and give interpretations of the data grounded in a relativistic “framing” idea, which MacLaury called Vantage Theory.

MacLaury employed the WCS methodology from 1978 up until approximately 2004. Subsequent to 2004 the archive containing the MCS was inactive, unlike that of the WCS, with its raw data

inaccessible to researchers while it was preserved in private storage by the MacLaury estate. Beginning in 2010 funding to initiate preservation and digitization of the archive was obtained. The initial preservation of the MCS archive, including its estimated 70 additional worldwide languages, came in the form of funding to purchase the archive from MacLaury’s estate, supported by the University of California Pacific Rim Research Program (award to K.A. Jameson, PI), and was augmented by a 2014 National Science Foundation funding (#SMA-1416907, K.A. Jameson, PI) that in part aimed to establish a public-access digital archive of transcribed MacLaury data and construct a user-friendly Wiki to generally facilitate collaborative color categorization research.

MCS Methodologies

Using individual samples and a color stimulus array shown in the WCS stimulus palette (see Fig. 1, Kay and Cook’s ECST entry), the MCS included three independent tasks done by every

native-language speaker surveyed. These consist of (1) a “naming task” that involved the free naming of 330 color samples presented in a fixed random order; (2) a “focus task,” identification of named category best exemplars or category “foci”; and (3) a “mapping task” that involved the demarcation of named category boundaries, producing a “boundary map.” The latter “mapping task” was used in Berlin and Kay’s original work, but for simplicity was omitted from the WCS. In the MCS, naming and focus data were collected for 900 individuals, and the mapping task method was reintroduced and assessed on an estimated 365 individuals. Data collection procedures used are detailed in works of MacLaury [28, 29] and are also similarly reviewed in WCS materials [2].

These MCS methods, along with the selection of languages it assessed, permit an unprecedented study of concept formation and linguistic representation, because of the following: (1) Many MCS languages are phylogenetically related to

Mesoamerican Color Survey Digital Archive, Fig. 1 Map depicting a portion of the geographic region surveyed by the MCS from the border of the United States to Nicaragua. Approximate locations of 116 MCS languages sampled are indicated as *blue crosses*, and 20 *red*

dots show WCS languages that duplicate some of the MCS languages surveyed. Of note are the dense samples of linguistically related MCS languages found in the areas of Oaxaca (37 languages), Guatemala (30 languages), and Mexico City (33 languages)

varying degrees. (2) Many MCS languages emphasize different perceptual dimensions (e.g., either primarily brightness or hue) and permit new analyses of dimensional salience. (3) Most MCS languages that satisfy (1) and (2) are related spatially, or geographically, and are thus known or expected candidates for linguistic borrowing, drift, and bilingual influences.

MCS Data

The research scope of the MCS data is substantial because it has features that can be exploited for addressing a range of heretofore unexplored color categorization research questions concerning how color categorization systems evolve, how semantic meaning drifts, and how meaning may be impacted by the influences of neighboring systems.

For example, Fig. 2's representation of one language family (Otomanguean, Glottolog: otom 1299) shows one example that is well represented in the MCS, and, like that shown in panel (a), the

MCS generally contains clusters of phylogenetically related languages, usually from contiguous geographic regions. Thus, for this one language family, as Fig. 2a illustrates, the MCS provides an estimated 369 surveyed participants, for which most subdivisions shown in panel (a) were assessed. Moreover, panel (b) illustrates that for some subdivisions, using Chinantec as an example, one may find several variations: That is, the MCS has six variations that cover three different levels of Chinantec language development/ endangerment.

In addition, the MCS also has many languages that emphasize different dimensions of color appearance space compared to the hue-based systems emphasized by languages typically investigated in the literature. For each language surveyed, the actual MCS datasets typically include detailed investigator notes or ethnographies, as well as the datasheets on the three tasks. Variations on information contained and

Mesoamerican Color Survey Digital Archive, Fig. 2 Example of the typical level of representation for one language family (Otomanguean) found in the MCS. Panel (a) shows a map of Oaxaca and Mexico City areas shown above in Fig. 1. Numbered color regions represent Otomanguean family language branches listed in inset (Retrieved on 12/02/2014 from “https://commons.wikimedia.org/w/index.php?title=File:Otomanguean_Languages.png&oldid=89424714”. Image: [wikipedia.org, https://commons.wikimedia.org/wiki/File:Otomanguean_Languages.png](https://commons.wikimedia.org/wiki/File:Otomanguean_Languages.png)) exemplifying spatial density of related languages that is typical of the MCS. Panel (b) shows one of the family branches found in (a), namely, #9 Chinantec. Panel (b)

shows a level of language diversity and complexity typical of the MCS. In this example, six forms of Chinantec data are illustrated in the MCS dataset. Panel (b)'s six color dots locate MCS Chinantec languages within the cloud of all living languages (i.e., *small dots*) in relation to a language's population (vertical axis) and its level of development or endangerment (horizontal axis). *Blue dots* are Developing (EGIDS 5) showing examples of Chinantec in vigorous use, *green dots* are Vigorous (EGIDS 6a) – unstandardized and in vigorous use among all generations. *Yellow dots* are In trouble (EGIDS 6b-7). (Chinantec living language data adapted and cited with permission from <http://www.ethnologue.com> [33]. Used by permission, © SIL International)

common formats of MCS datasheets are now described and illustrated:

1. **Naming task:** Informants were asked to name 330 loose color chips in a fixed random order. While investigators conducting the survey tended to employ two datasheet formats for collecting naming data, individual variations do exist in the raw datasheets. Figure 3 shows two common raw datasheet formats used to collect naming task data. Image scans of raw MCS datasheets, and for a currently limited number of cases their transcribed digital data files, are provided on the archive website (detailed below).

Figure 3a, b show two common examples of MCS naming task datasheet formats as raw pdf image scans of the data. Panel (a) illustrates only one page (samples 1–81) surveyed from informant #1 (assessed in Guarijio language) showing a “list format” in which the investigator sequentially listed a participant’s responses to 330 samples evaluated in the fixed random order in which they were assessed. Panel (b) shows a second common format in which the investigator reports the participant’s responses to 330 samples, evaluated in the same fixed random order, in the appropriate row/column location on the MCS stimulus palette (see Fig. 1 in ► “World Color Survey”). The palette format of the naming task data often has participant’s “focus” choices embedded in the datasheet as can be seen in panel (b)’s column 0 which has a “circled-X” symbol shown in cells *A0* and *J0*, recording the “foci” indicated by this participant for color appearances which in English language would gloss as the focus of “white” and the focus of “black,” respectively.

2. **Focus selection task:** Informants were shown the entire 330 color stimulus palette and asked to select the best example, or focus, of each different color name elicited in the naming task (see [28, 29] for method details). Again, individual variations do exist in the raw datasheets. Figure 4 shows two common raw datasheet formats used to collect focus selection task data. In panel (a) focus task data is reported in

conjunction with naming task data, whereas in panel (b) focus selection task data is combined with mapping task data (mapping task is detailed below). In both formats shown in Fig. 4, focus selections are indicated by either a “circled-X” symbol (panel (a)) or by a plain “X” symbol alone (as in panel (b)). In focus task datasheets, it is common to find a dictionary of color terms elicited at the bottom of the sheet (as seen in both Fig. 4 panels). Mapping task datasheets most frequently delineate mapped category areas using hatched markings (e.g., Fig. 4b); however these data were also often recorded using color pencils (as shown in Fig. 5 and described in the next section). As with the naming task data, image scans of raw MCS datasheets, and transcribed digital data files for focus data, are provided on the archive website.

3. **Category mapping task:** For the same color category terms as in the focus selection task, informants were shown the entire 330 color stimulus palette and asked to indicate the regions of the stimulus palette in which the appearance of a given color term was represented. The informants in this way would map the color category stimulus regions glossed by each color term for which an investigator solicited a mapping (see [28, 29] for method details). This task is also referred to as the rice mapping task in the literature, because grains of rice were often provided to informants to mark the many stimuli that were denoted by a given color term. Figure 5 shows two raw datasheets, for Guarijio and Chinantec languages, illustrating, above and beyond data variations, slight variations in the ways investigators recorded the surveyed information. Again, in some cases Focus locations are recorded, whereas in other Mapping Task datasheets Foci are not recorded. In mapping task datasheets, it is common to find a dictionary of color terms elicited at the bottom of the sheet and a pseudo-color code legend is given to interpret the regions defined using a particular color pencil as belonging to a specific color term (as seen in both Fig. 5 panels). (In such pseudo-color codes, the color of the

ink used is not to be construed as resembling the color of the category data that it encodes.) As with the other MCS data, image scans of raw MCS datasheets are provided on the archive website.

The above details of MCS data, including Figs. 3, 4, and 5, convey the kind of coding variation found throughout the datasheets in the MCS archive. The variation is not wholly unexpected as a large number of the 116 languages of the MCS were collected by different investigators, at different locations, over the approximately 5 years during which the MCS was conducted. Notwithstanding this amount of idiosyncratic coding style, the MCS raw data, as well as the rest of the MacLaury archive, appear to be of rather consistent and thorough formatting concerning the data that is collected, especially considering the mass of information that exists in the estimated 20,000 pages of the archive.

The MCS and the Robert E. MacLaury Color Categorization Digital Archive (ColCat)

Recognizing the value in the MCS data, the interdisciplinary *ColCat* research group at UC Irvine sought to convert the paper copy of MacLaury's research archive into a public-access digital database, similar to that developed for the WCS by Paul Kay and colleagues [2]. The entirety of MacLaury's MCS data is included in this *ColCat* digital archive [34]. A major aim of the *ColCat* project is to develop a platform to make the archive, including the MCS data, readily available to the scientific research and teaching community. The project presently makes available organized sets of scanned image files of datasheet pages in the archive acquired from MacLaury's estate and continues to implement an intuitive Internet-based user interface to serve as the front end of a collaborative research space with which researchers can readily explore and investigate their own basic research questions concerning the MCS data, as well as the color

categorization data from other languages that MacLaury assessed. As mentioned earlier, neither the raw MCS data nor the MacLaury archive's additional non-Mesoamerican languages have been systematically organized for public use or previously published in an unanalyzed form. The additional 70 color categorization surveys (many with only a single informant, although others with frequently many more, and the largest with 40 informants) are valuable for their diversity in that they include native speakers from a wide range of languages including several Slavic languages, Hungarian, several Salishan languages of the Pacific Northwest United States, Zulu and several other South Africa/Zimbabwe languages, several native American languages, Germanic languages, European languages, Asian languages, and more.

The *Robert E. MacLaury Color Categorization (ColCat) Digital Archive* uses a content management system (CMS) for organizing, editing, and publishing the contents of the archive to a web-based graphical user interface (GUI) hosted at <http://colcat.calit2.uci.edu>. A partial list of features provided for the MCS through *ColCat* is summarized below:

1. User access level permissions and controls for the archive areas of the Wiki. User logins that define various levels of access for researchers, including those who may only want unregistered access to view database contents. Member level access for registered users who want to interact with the database. Editor level access as a trusted contributor to the database. Administrator access for systems operators who maintain database changes and review and approve contributions made by editor level users. Proper controls are implemented to maintain long-term integrity of the archive and to forestall loss and corruption of datafiles as well as accidental losses of data.
2. Facilitated search and query tools for exploring aspects of the datasets such as language type, language family, specific color terms, participant group subsets (e.g., by gender, age, etc.), survey

- geographic locations, and other filters that have been specified by content in the archived data.
3. Transcription quality indicators for evaluating conversion accuracy of handwritten data content into digitally addressable datasets. Because there are several ways the raw handwritten data in the archive can be converted into data addressable digital files (e.g., manual transcription, crowdsourced transcription, optical character recognition or OCR-based transcription, linguistic expert transcription, etc.), a useful feature of the ColCat Wiki includes utilities that permit assessment of each dataset's transcription quality and comparison across multiple forms of transcription of the same dataset. Transcription quality indicators appear on every surveyed language's archive page, and, where appropriate, indicate the degree of transcription completion, and computed degree accuracy, for each language's transcribed datasets.
 4. To encourage users to explore the archive's original raw datasheets, the *ColCat Wiki* provides each survey's scanned image files of the archive's raw data organized in a browsable catalog/library of pdfs (like those seen in Figs. 3, 4, and 5 above). Onboard pdf files of raw datasheets permit visual inspection of investigator's ethnographic notes and embellishments; verification of digitized data content; and querying pdfs by language family, language type, location and so forth, as well as querying by combinations of such tags.
 5. An onboard suite of supporting resources for color categorization research. For example, (a) on every surveyed language's archive page (where appropriate and provided for by the archive's contents), maps of the geographic regions are provided where surveys were conducted, permitting visualization of geographical relatedness among the archive's datasets, as well as allowing for search and identification of database contents by exploring geographical locations (via a Google Map plugin) where the actual survey data originated. (b.) Bibliographic resources highlighting specific languages or language families, including lists of peer-reviewed journal publications, books, relevant media, and reference materials, provided for each of the archive's languages surveyed. (c.) Active links out to relevant Internet resources, such as *World Atlas of Language Structures Database* (<http://wals.info>), and the public-access site *Ethnologue: Languages of the World Database* (<http://www.ethnologue.com>).
 6. As mentioned above a major aim of the archive project was to develop a platform to make the archive's data readily available to the scientific research and teaching community. Toward this end, the archive is designed to function as a collaborative research space, with user contributions enabled for trusted contributors, an informal blog feature to encourage a community of research exchange, and a platform for sharing and communicating results and for collective problem solving.
- Additionally important was the aim of making the digital archive's data accessible to a broad audience comprised of users with varying levels of expertise in handling and analyzing large amounts of data. For this reason, a set of *ColCat data tools* was developed which allow users to search, filter, and analyze data in ways that best meet their research goals and technical abilities.
- The planned data-handling tools and utilities aim to facilitate, for all user levels, the use of the archive's contents for original color categorization research studies.
- The ColCat digital archive, including the MCS, contains data at three levels:
1. Digital image scans, in pdf format, of approximately 12,500 handwritten pages of color-naming data, ethnographic notes, and support documents from 116 Mesoamerican languages, plus pdf image scans of an additional 10,000 pages surveyed globally from other languages and nations
 2. Raw transcription data of these surveys converted and collected through OCR, crowd sourcing, and expert transcribers, and

3. “Official” transcription conversions for the archive’s color-naming and categorization data

The Wiki’s onboard data tools are designed for visualizing and analyzing the computer-addressable archive data at levels 2 and 3. Visualization tools for transcription data (level 2) include quantitative indicators of completeness and quality of transcriptions for each language and visualizations of the variance between or within transcription methods for entire languages or subsets of images within a language. Visualization tools for color-naming data (level 3) will include visualizations of the aggregated color-name mappings for each language including information about the proportion of agreement among all respondents or subsets of respondents through the use of filters – i.e., based on gender, age, etc.

Data export tools will allow users to download both transcription and naming data (levels 2 and 3) in formats conducive to off-line analysis (i.e., CSV, Excel, etc.). Although information about aggregated color-name mappings (level 3) will be based on data from all subjects in a language, users may be interested in computing and/or comparing consensus color-name mappings for subpopulations based on their own criteria. To that end, downloadable tools will allow users to take the same analyses and visualizations that are used on the Wiki for complete populations and apply them to subpopulations that were exported by the user. The expectation is that a variety of user types will employ the Wiki’s visualization tools to help identify subsets of data in the archive that meet specific research goals, while other researchers will be more inclined to export data in a familiar format (i.e., in an established WCS format) and apply their own off-line analyses. Regardless of the case, the ColCat data tools make the entire archive’s data accessible to a wide range of researchers, students, and other scientists who would like to explore and learn from the archive but are not well equipped to manage and process large quantities of data.

Uses of the MCS Archive

As a complementary database to the World Color Survey database, the addition of the MCS archive allows for an even greater, more extensive, assessment of behaviors of cross-cultural color cognition and color naming. For example, reconsider the Fig. 2a discussion above, concerning the 369 surveyed Otomanguean language family informants for which MCS data exists. These MCS informants can now be independently compared to, or even analyzed in conjunction with, the 175 previously surveyed WCS informants from the Otomanguean language family. In addition to the novel surveys it adds, it is this kind of duplication and augmentation that the MCS provides as a complementary database to the WCS that will increase the value of both archives and present new opportunities to greatly extend understanding of how the data in the MCS and the WCS inform on the questions originally asked by the surveys’ directors, namely, what specifically are the universal and culturally specific patterns of color naming and categorization that can be empirically demonstrated for large samples of the world’s diverse languages and how do they inform us on the larger question of general human tendencies for categorizing and naming objects perceived in the world.

Metal Halide Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Definition

A lamp that produces light as a result of an electrical discharge, generated between two electrodes, in a high-pressure mercury vapor with metal halide additives that is contained in a transparent bulb.

Metal Halide Gas Discharge Lamps

Metal halide lamps are high-pressure mercury gas discharge lamps that contain metal halides in addition to the mercury [2, 3]. In the heated discharge tube, the metals of the halides take part in the discharge process and radiate their own spectrum. Compared with high-pressure mercury lamps, both color properties and efficacy are considerably improved. Thanks to the fact that no fluorescent powder is needed, the small gas discharge tube itself is the light-emitting surface. This small light-emitting surface makes the lamps extremely suitable for use in reflector and floodlight luminaires. Initially, they were solely produced in extremely high lumen packages with relatively large lamp dimensions (about the size of a 1-liter bottle). These lamps are particularly suited for use in floodlights for the lighting of stadiums. Today, compact metal halide lamps are also available in small lumen packages, which make them very suitable for use in compact reflector luminaires for accent lighting both indoors and outdoors. These versions have become an energy-efficient alternative for halogen lamps. Special compact metal halide versions are being produced for use

in film studios and theatres. The smallest metal halide lamps are used for car headlamps (these are the so-called xenon lamps, whose gas discharge tube is no larger than a match head). Metal halide lamps belong to the group of high-intensity discharge (HID) lamps because they are available in high-lumen output (and thus high-luminous-intensity) versions.

Working Principle

Suitable metals that vaporize in the hot discharge tube so as to contribute to the discharge process cannot be added directly to the mercury in the discharge tube. This is because metals suitable for this purpose attack the wall of the gas discharge tube at the high temperatures that are needed for the gas discharge to occur. The solution to this problem is to add these metals in the form of their nonaggressive chemical compounds with a halogen (iodine, bromide, or chloride), hence the name metal halide lamps. The solid metal halide starts evaporating once, after switching on the lamp, the mercury discharge has increased the temperature in the discharge tube. When this metal halide vapor enters the area of the mercury discharge in the center of the tube with its very high temperature (around 3,000 °C), it dissociates into its separate elements: metals and halogen. There the metals in their pure, vaporized state take part in the discharge process and determine the efficacy and color characteristics of the radiation. The aggressive vaporized metal cannot reach the tube wall because, at the lower wall temperature (some 1,000 °C), they recombine again to form the harmless metal halide compound. Like all gas discharge lamps (with very few exceptions), a metal halide lamp cannot be operated without a ballast to limit the current flowing through it. It also needs, again like most gas discharge lamps, an igniter for starting the lamp.

Materials and Construction

The main parts of a metal halide lamp are (Fig. 1):

- Discharge tube
- Metal halide additives
- Fill gas

Metal Halide Lamp,
Fig. 1 Main parts of a
 metal halide lamp [1]

Metal Halide Lamp, Fig. 2 Gas discharge tube made of quartz (*left*) and ceramic material (*right*), respectively. The yellow material seen through the quartz tube is condensed metal halide [1]

- Outer bulb
- Electrodes
- Lamp cap

Discharge Tube

The discharge tube is made of either quartz or ceramic material. Some metals of the metal halide compounds (especially sodium) have the tendency, at high temperatures, to migrate slowly through the quartz wall of the tube, with the result that there is a gradual change in the color properties of the lamp during its lifetime. The use of ceramic discharge tubes solves the problem. Such tubes are impervious to these metals, even at high operating temperatures. High-pressure sodium lamps make use of the same ceramic material. Metal halide lamps using ceramic material are referred to as ceramic metal halide discharge lamps. Figure 2 shows examples of both quartz and ceramic gas discharge tubes. Since the ceramic tube is produced by sintering minuscule aluminum-oxide particles, one cannot look straight through the wall, although the light transmittance is more than 90% (translucent instead of transparent material). Ceramic gas discharge tubes are operated at a higher temperature than are quartz tubes. The higher operating

temperature influences the spectrum of the radiation. The result is a lower color temperature compared to that of quartz metal halide lamps and a 10% higher efficacy.

Metal Halide Additives

In theory, some 50 different metals can be used for metal halide compounds, and different manufacturers have introduced various combinations of these metals. Examples of some of the metals used in metal halide compounds are sodium, thulium, thallium, indium, scandium, dysprosium, and tin. Most lamps use a mixture of at least three different metal halides. Each different combination results in a different spectrum, but also in different efficacy, lumen maintenance, and lifetime characteristics.

Fill Gas

Besides metal halides and mercury, an inert gas is also added to the discharge tube, like in most other discharge lamps.

Electrodes

The electrodes of metal halide lamps are of the type used in ordinary high-pressure mercury lamps. They consist of a tungsten rod, with a

tungsten coil impregnated with emissive material, wound around it. They are of more massive construction than the ordinary high-pressure mercury lamps because of the higher operating temperature.

Outer Bulb

Most metal halide lamps use a hard glass or (for very compact versions) quartz outer bulb for protection and for heat insulation of the discharge tube. Both single-ended and double-ended outer bulbs are used (Fig. 3). They may be evacuated or gas-filled. In the case of quartz outer bulbs, UV-blocking quartz is used to limit harmful UV radiation. For the same reason, some hard glass versions use a cylindrically shaped UV-block shield around the discharge tube.

The inner wall of the outer bulb reflects a very small part of the light that consequently cannot be very well controlled by a luminaire reflector. But since the reflected amount is so small, this usually is not a problem, except where very-high-lumen-output lamps are employed. In floodlight installations, a very small amount of uncontrollable light could give rise to disturbing light pollution. For these applications special lamps are therefore available that have no outer bulb (Fig. 4). For reasons of thermal stability and safety, those lamps without an outer bulb must be used in specially designed luminaire housings.

Metal Halide Lamp,

Fig. 3 *Top* tubular hard glass, single-ended outer bulb and *bottom* quartz, tubular double-ended outer bulb

Metal Halide Lamp, Fig. 4 Double-ended quartz metal halide lamp not making use of an outer bulb

Lamp Caps

Metal halide lamps come with a great variety of lamp caps (Fig. 5). The single-ended lamps of higher wattage have in general E40 Edison screw caps. Some caps have special electrical insulation because of the high ignition pulses of between 600 and 5,000 V. The lower-wattage single-ended lamps have two-pin electrical connections of various types, sometimes with ceramic electrical insulation. In order to be able to accurately position the gas discharge arc in a luminaire, some lamps are provided with a so-called prefocused lamp cap (Fig. 5, right). The double-ended lamps use lamp caps of the type that are also used in double-ended halogen lamps (Fig. 3, bottom). The lamps without an outer bulb again have different lamp caps (Fig. 4).

Properties

Energy Balance

Almost 25% of the input power of metal halide lamps is emitted in the form of visible radiation. Compare this with 15–17% of normal high-pressure mercury lamps and 30% of high-pressure sodium lamps.

System Luminous Efficacy

The compact versions of the metal halide lamp have lumen efficacies (depending on the metal

Metal Halide Lamp,**Fig. 5** Various lamp caps for compact single-ended metal halide lamps

halide mixture and gas discharge tube material used) of between 70 and 95 lm/W. When comparing this with ordinary halogen incandescent lamps with their maximum efficacy of 25 lm/W, it is clear that compact metal halide lamps are often very suitable to replace halogen lamps. The larger versions of metal halide lamps have efficacies from some 75 lm/W to slightly more than 105 lm/W.

Lumen Package Range

Compact versions are available in lumen packages from some 1,500 to 25,000 lm (corresponding wattage range 20–250 W). Larger versions range from some 20,000 lm to more than 200,000 lm (corresponding wattage range 250–2,000 W). Special (compact) types for use in film studios, theatres, and professional photography are produced in lumen packages of up to more than 1,000,000 lm (12 kW).

Color Characteristics

As has been explained in the sections above, by employing different metal halide mixtures, lamps with different spectra can be produced. Like all gas discharge lamps, the metal halide lamp has a discontinuous spectrum. Figures 6, 7, and 8 show the spectra of some typical metal halide lamps with different color temperatures T_k and color rendering index R_a . The same color

designation system is used as with fluorescent lamps.

Compact metal halide lamps are typically produced in the color temperature range of 3,000 K to some 4,500 K in two color rendering varieties: R_a ca. 80 and ca. 90. The larger metal halide lamps are available in the color temperature range from approximately 4,000 to 6,000 K, with color rendering R_a in the range from 65 to more than 90. The special, daylight, metal halide lamp types for film studio and theatre lighting have high color temperatures of between 6,000 and 8,000 K with color rendering values R_a between 65 and more than 90.

Lamp Life

The lamp life of most metal halide types is somewhat shorter than that of other gas discharge lamps. This is because the electrodes are heated to a higher temperature with a correspondingly higher evaporation rate and are gradually worn out by chemical reactions with the metal halides. It has also been shown that different metal halide lamp types employ widely different construction methods. As a consequence, lamp life varies strongly with type. The economic life of compact versions lies between some 7,000 and 14,000 h (20% mortality). The high-lumen-package versions vary from 4,000 h (single-envelope types for stadium floodlighting) to some 10,000 h (again

Metal Halide Lamp, Fig. 6 Spectral energy distribution of a metal halide lamp, color type 642: T_k 4,200 K and R_a 65 [1]

Metal Halide Lamp, Fig. 7 Spectral energy distribution of a ceramic metal halide lamp, color 830: T_k 3,000 K and R_a 80 [1]

Metal Halide Lamp, Fig. 8 Spectral energy distribution of a ceramic metal halide lamp, color 942: T_k 4,200 K and R_a 90 [1]

20% mortality). These ceramic metal halide lamps specifically developed for use in road lighting, where lights may be used 4,000 h a year, have lifetimes up to 20,000 h (20% mortality).

Lamp Lumen Depreciation

Metal halide lamps have a higher lumen depreciation than most other discharge lamps. This is because of the higher degree of blackening from evaporated electrode material. Here too, the type of construction and sort of metal halides used to play a role. Lumen depreciation values vary between some 20% and 30% (after 10,000 h). Some special types, such as those employed in road lighting, depreciate less rapidly (some 10% after 10,000 h).

Burning Position

With the larger gas discharge tubes, in particular, the burning position may affect the actual location of the various metals in the tube. This means that different burning positions may result in different color shifts. Also, with some types of lamp construction, the burning position can influence the lifetime of the lamp, for example, because of attack of the electrodes by some of the metals of the halides. Many metal halide lamps, therefore, have restrictions as to their permitted burning position (these are, of course, specified in their accompanying documentation). Compact, single-ended types, with either quartz or ceramic tube, have universal burning positions.

Run-Up and Reignition

The metal halides in the discharge tube need time to heat up, evaporate, and dissociate into metal and halide. During this process, which takes about 2–3 min, the light output and color gradually change until the final stable condition is reached. If there is an interruption in the power supply, medium- and high-wattage lamps will take approximately 10–20 min for the pressure in the lamp to decrease enough for it to reignite. Compact ceramic lamps reignite much faster: after some 3–5 min. Immediate reignition is only possible by applying a very high-voltage pulse

(typically 60 kV). For this purpose, special, hot restrike, lamps are produced with special heavily insulated electrical contacts for applying this high-voltage pulse.

Dimming

The dimming of metal halide lamps is difficult because, with the resulting decrease in temperature, some of the metal halides condense, changing the constitution of the metal halides actually participating in the discharge. This, in turn, changes the color properties of the light. By employing a specially shaped burner, electronically driven lamp versions have been developed that can be dimmed to some 50% without suffering from this problem.

Mains Voltage Variations

Mains voltage variations affect lumen output, lifetime, and light color. A mains voltage that deviates 10% from its nominal value will result in perceivable color shifts. Thanks to the higher operating temperature of ceramic lamps, the effect on color change here is considerably smaller. Both up and down variations in the mains shorten lamp life.

Metal Halide Lamp, Table 1 Different metal halide lamp types

Lamp parameter	Range
Lamp size	Medium/compact/very compact
Discharge-tube material	Quartz/ceramic
Lamp shape	Single-ended/double-ended
Outer bulb	Outer bulb/coated outer bulb/no outer bulb
Lumen package	Large/small
Lamp circuit	Electromagnetic/HF electronic
Color temperature T_k	3,000–4,000 K/4,000–7,000 K
Color rendering index R_a	$R_a > 90$ (900 series)/ $80 < R_a < 90$ (800 series)/ $R_a < 80$
Lifetime	Standard (7,000–14,000 h)/long (up to 20,000 h)
Reflector	No reflector/built-in reflector

Metal Halide Lamp, Fig. 9 Examples of metal halide lamps used mainly in indoor lighting

Metal Halide Lamp, Fig. 10 Examples of metal halide lamps used mainly in outdoor lighting. *First three:* for road and industrial lighting. *Last four:* for sports floodlighting

Product Range

Metal halide lamps are available in a wide variety of types for many different applications, including floodlighting, road lighting, accent lighting (both interior and exterior), car head lighting, and film studio lighting. The more important lamp parameters, together with the corresponding range for which different versions are made, are listed in Table 1. Figure 9 shows some examples of lamp types used mainly in indoor lighting, while Fig. 10 shows those types primarily used in outdoor lighting.

Metamerism

Peter van der Burgt

Philips Lighting, Valkenswaard, The Netherlands

Definition

Metamerism is the matching of apparent color of objects with lights that have different *spectral power distributions*. Colors that match are called metamers.

Color of the Light

The light coming from any light source (sunlight, incandescent lamp) can be described by the so-called spectral power distribution, often denoted as SPD. The SPD gives the amount of power radiated by the light source as a function of wavelength in the visible range of the electromagnetic spectrum being 380–740 nm. Every SPD will generate a color impression in the human visual system. To describe the color of the light, a system has been developed by the CIE (Commission Internationale de l'Eclairage). A set of three color-matching functions called $x(\lambda)$, $y(\lambda)$, and $z(\lambda)$ has been defined, and these are known collectively as the CIE standard observer [1]. These color-matching functions are depicted below in Fig. 1.

By using the color-matching functions, the effect of a *spectral power distribution* $E(\lambda)$ can be expressed by the following equations:

$$X = \sum E(\lambda) \cdot x(\lambda) \quad (1)$$

$$Y = \sum E(\lambda) \cdot y(\lambda) \quad (2)$$

$$Z = \sum E(\lambda) \cdot z(\lambda) \quad (3)$$

The values X , Y , Z are called the tristimulus values of the color of the light with spectral power distribution $E(\lambda)$.

The tristimulus values for a light can be converted to the chromaticity or color point x , y by the following equations:

$$x = X/P \text{ with } P = X + Y + Z \quad (4)$$

$$y = Y/P \quad (5)$$

These equations lead to the well-known CIE chromaticity diagram which is shown in Fig. 2. With the equations above, the color points for monochromatic lights can be calculated. This leads to the spectral locus, the outer curved boundary in the diagram. The straight edge on the lower part of the gamut is called the line of purples. These colors, although they are on the border of the gamut, have no counterpart in monochromatic light. Less saturated light colors appear in the interior of the figure. The diagram shows in

Metamerism,
Fig. 1 Color-matching
functions CIE

Metamerism, Fig. 2 CIE chromaticity diagram

the colored area all the chromaticities that are visible to the average person, and this colored region is called the gamut of human vision. One important property of this diagram is that lights that have the same chromaticity will give the same color impression to an observer. The chromaticity, however, does not predict the precise color impression of a light. For example, an incandescent lamp burning in the middle of the day may give a yellowish impression. The same lamp in the night will yield a white impression. So the precise color impression will depend on the adaptation of the observer. But at the same adaptation, the same chromaticity will lead to the same color impression.

Metamerism of Light Colors

Equations 1, 2, and 3 show that it is possible that more lights having different SPDs can nevertheless have the same values for the tristimulus values X, Y, Z and, therefore, the same chromaticity. Such lights are called metamer; they have different spectral power distributions but give the same color impression. It should be noted that this

metameric character applies within the boundaries of the CIE XYZ system.

Metamerism of Object Colors

The spectral composition of a color stimulus of an object color can be described by the following equation:

$$E_R = \beta(\lambda) * E(\lambda) \tag{6}$$

with

$E(\lambda)$: spectral power distribution of the light that illuminates

$\beta(\lambda)$: spectral reflectance of the object (fluorescent objects will be neglected here)

The tristimulus values of this color stimulus are as follows:

$$X = \sum \beta(\lambda) * E(\lambda) . x(\lambda) \tag{7}$$

$$Y = \sum \beta(\lambda) * E(\lambda) . y(\lambda) \tag{8}$$

Metamerism, Fig. 3
(a–c) Change of light source leads to change in color appearance

$$Z = \sum \beta(\lambda) * E(\lambda).z(\lambda) \tag{9}$$

Suppose the amount of light on the object is decreased with a factor 10, so $E(\lambda) = 0.1E(\lambda)$. From experience, it is known that the human

visual system adapts in such a way that the color impressions stay the same.

Now suppose that the spectral reflectance is reduced with a factor 10, so $\beta(\lambda) = 0.1 \beta(\lambda)$. Again from experience, it is known that the color

impression will change: a white will turn into a gray, an orange color will turn brownish, etc.

How to account for these two observations? This can be done by defining the tristimulus values of object colors by the following equations:

$$X = 100 * \sum \beta(\lambda) * E(\lambda) . x(\lambda) / \sum E(\lambda) . y(\lambda) \quad (10)$$

$$Y = 100 * \sum \beta(\lambda) * E(\lambda) . y(\lambda) / \sum E(\lambda) . y(\lambda) \quad (11)$$

$$Z = 100 * \sum \beta(\lambda) * E(\lambda) . z(\lambda) / \sum E(\lambda) . y(\lambda) \quad (12)$$

By defining the values like this, they have become invariant for multiplication of $E(\lambda)$ with a constant factor, so invariant for the light level.

At the same time, multiplication of $\beta(\lambda)$ with a constant factor will lead to accordingly changes in the tristimulus values of the object color.

Another way of doing this is by normalizing $E(\lambda)$ in such a way that

$$\sum E(\lambda) . y(\lambda) = 100 \quad (13)$$

Normalizing $E(\lambda)$ like this enables the use of Eqs. 7, 8, and 9 to calculate the tristimulus values.

For light sources, the light color can be defined with only two coordinates, the chromaticity x, y .

For color stimuli of object colors, however, three coordinates are necessary. These can be X, Y, Z or x, y, Y or any other three-dimensional system.

Object colors will be metameric if the three tristimulus values of the colors will be equal.

Suppose two object colors have spectral reflectances $\beta_1(\lambda)$ and $\beta_2(\lambda)$. These object colors will be metameric under a light $E(\lambda)$, normalized like in Eq. 13, if

$$\begin{aligned} X_1 &= \sum \beta_1(\lambda) * E(\lambda) . x(\lambda) \\ &= \sum \beta_2(\lambda) * E(\lambda) . x(\lambda) = X_2 \end{aligned}$$

$$\begin{aligned} Y_1 &= \sum \beta_1(\lambda) * E(\lambda) . x(\lambda) \\ &= \sum \beta_2(\lambda) * E(\lambda) . x(\lambda) = Y_2 \end{aligned}$$

$$\begin{aligned} Z_1 &= \sum \beta_1(\lambda) * E(\lambda) . x(\lambda) \\ &= \sum \beta_2(\lambda) * E(\lambda) . x(\lambda) = Z_2 \end{aligned}$$

These object colors are metameric under the light with spectral power distribution $E(\lambda)$. It is clear that the metameric character depends on the light source. In general, with another light with a different SPD, the relations $X_1 = X_2, Y_1 = Y_2$, and $Z_1 = Z_2$ will no longer hold. This means that colors metameric under one light source, that is, giving the same color impression, can look rather different under a light source with a different SPD. This is illustrated in Fig. 3. Two brown textiles with different reflectances will have the same color appearance in daylight, whereas in a specific fluorescent light, the color appearance will be different. In Fig. 3b, c, the reflectances of the colors are depicted together with the spectral power distributions of daylight and fluorescent light.

In the paint industry, metameric object colors are very well known. In this industry, a frequently occurring problem is to reproduce a color with other pigments than the ones used for the original color. In such cases, usually samples are sought that are metameric under daylight as well as incandescent light.

Minimally Distinct Border

Michael H. Brill
Datacolor, Lawrenceville, NJ, USA

Definition

In an exactly abutting pair of spatially uniform colored regions, if one of the regions is varied in radiance until the border between the regions is least conspicuous to a human observer, that border becomes a minimally distinct border (MDB) and is seen as having maximal blur and minimal contrast. The term MDB is used both for the border itself and for the psychophysical method used to derive it.

Historical Beginnings

The minimally distinct border was first reported by Boynton and Kaiser [1] in connection with psychophysical experiments. From the beginning, it was realized that the condition of MDB occurs when the two abutting regions have the same luminance. Hence, the condition of MDB is best understood in terms of the properties of luminance. (See next section.)

However, the history of the MDB is not just about luminance [2, 3]. The MDB was first used in an attempt to quantify complete color differences regardless of their size. Previously, whereas small color differences could be quantified by

discrimination thresholds, large color differences were assessed by magnitude estimation. Compared to magnitude estimation, the assessment of strength of a visual border seemed to offer greater precision. In such experiments, subjects were asked to define the achromatic contrast that they deemed as equivalent to the chromatic contrast of a given border. When the radiances were titrated so as to produce a condition of MDB – hence equality of luminance – one could then look at the strength of the border as a function of the other color coordinates. Historically, MDB experiments tended to compare a monochromatic light with a reference white, so it was thought that the MDB in such cases quantified saturation or departure from the white. As technology developed to present more light at shorter wavelengths (470 nm and lower), it was observed that the MDB could quantify only a “tritanopic saturation,” because no short-wave-sensitive (blue-sensitive) photoreceptors contributed to MDB. In fact, the MDB was observed to vanish completely for lights that were the same in all but their short-wavelength content – hence the name “tritanopic,” which derives from the nomenclature of color blindness. To quote Boynton [2]: “The blue-sensitive cones [...] seem to be free of any serious spatial or temporal responsibilities in vision.”

Luminance and MDB

Luminance of a light was initially thought to be linear in the light’s radiance and to transform perceptually to its brightness. Following this definition, two spectrally different lights were declared to have the same luminance if the radiance of one light was adjusted so its brightness matched the brightness of the other light. Early in the twentieth century, a more precise definition for luminance was devised: Two lights are equally luminous if, when the lights are presented alternately, the perceived flicker vanishes at the lowest frequency of alternation. The practice of finding equally luminous lights using this definition is called flicker photometry.

To be in harmony with both these definitions, in 1924, the Commission Internationale de

l'Eclairage (CIE) developed a hybrid definition based on experiments of both sorts: flicker fusion of two alternating lights and direct brightness comparison of two lights at neighboring wavelengths [4]. As defined by the CIE, the luminance of any light is proportional to the integral of its spectral power distribution weighted by a function $V(\lambda)$ (called the luminosity function) derived from these experiments.

In the next 30 years, it was discovered that $V(\lambda)$ could not capture all the facts about isoluminous lights. For one thing, Deane Judd found in 1951 that $V(\lambda)$ should be modified to have a larger contribution at short wavelengths. Also, the physical size of the light stimulus (field size) was found to have an influence on luminosity, as testified by the 1964 CIE colorimetric standard that was tailored to a 10° field size rather than to the 2° field size previously used. Finally, the luminosity of lights at low (scotopic) radiance follows the spectral sensitivity of the rods rather than the cones of the visual system. The low-light limit of luminance also entailed a transition to the high-light limit through a radiance domain known as the mesopic, in which both rods and cones operate.

Clearly the 1924 CIE definition of luminosity, although ubiquitous in industrial and other practical usage, diverges from what is found in actual visual systems. Therefore, vision researchers prefer to define luminance according to an empirical criterion, such as implied by flicker photometry. Once this definition is adopted, it is found that various other visual phenomena depend only on luminance of the stimulating light. In particular, visual acuity is a function only of luminance. In fact, the evidence supports the characterization of luminance as a channel in human vision, fed by long- and medium-wavelength-sensitive cones, occasionally by rods, and never by the short-wavelength-sensitive cones. The luminance channel is tuned to stimuli of the highest spatial and temporal frequencies perceivable by the visual system.

Using the vision-science definition of luminance described above, the condition of MDB between two abutting light patches occurs when the patches have the same luminance.

Measuring MDB

An MDB experiment finds the relative luminance of a light field as follows. For a fixed reference field, the MDB radiance of a monochromatic test field at wavelength λ is measured. The ratio of the reference to test radiance at MDB is proportional to the test field's luminance as a function of wavelength.

The MDB used in this way can be an empirical definition of luminance. In fact, because MDB presents the test and reference stimulus simultaneously, it has been touted as superior to flicker photometry as a method of measuring luminance.

MDB studies have been done over a variety of geometric conditions. Typically, the experiments involve a bipartite field of two semicircles (test field and reference field). The semicircles meet at a diameter on which the subject is directed to fixate. Alternatively, if one wants to compare the strength of an MDB with the strength of an achromatic border, one can divide the field into quarters of a circle, the top two comprising the achromatic border and the bottom two comprising the chromatic MDB.

It should be noted that creating the geometric conditions for MDB is not trivial. For example, an achromatizing lens is recommended to remove chromatic aberration, which would otherwise disturb the edge between the abutting fields.

Physiological Basis

The measurement of MDB was possible in macaque retina under several experimental conditions, most notably when the border was moved back and forth in the macaque's visual field. Two kinds of retinal mechanisms, fast (phasic) and slow (tonic), were examined as possible vehicles for MDB, and evidence favored the phasic mechanism [5].

As with any psychophysical measure of luminance, additivity (i.e., Abney's law) has been found to be imperfect, but this is hardly surprising since the luminance channel in vision receives inputs from more than one cone channel, and cone response is nonlinear in light intensity.

Furthermore, the low-luminance limit must engage the rods as well as the cones, so additivity cannot be a strict property of MDB.

Extension to Mesopic Photometry

Raphael and MacLeod [6] discovered that equating luminance at various mesopic radiance levels (in which both rods and cones enter the function) is correlated strongly with achieving MDB at these levels.

Monochromator

Yi-Chen Chuang

Center for Measurement Standards, Industrial Technology Research Institute, Hsinchu, Taiwan

Definition

A monochromator is an optical dispersing device that is used to select a narrow band of light (i.e., optical radiation) from a wider range of wavelengths available at the input. The Greek roots “mono-” and “chroma-” refer to “single” and “color” respectively. Ideally, a monochromator should produce a single wavelength of optical radiation at its output. Although lasers produce light that is much more monochromatic than the optical monochromators discussed here, only some lasers are easily tunable but are not as simple to use.

Monochromators are included in many optical measurement instruments and systems for applications where tunable monochromatic light is required. A monochromator combined with optical detectors can be used to obtain the spectral power distribution (SPD) of light sources, reflectance or transmittance of objects, etc.

Monochromators are important for color measurement because many color-related optical characteristics are dependent on wavelength.

In color science, reflected or transmitted light from a sample is usually measured, where a monochromator can be used before or after the incident light illuminates a sample. If a monochromator is used before the incident light illuminates the sample, the incident light is monochromatic light. On the other hand, if a monochromator is used after the light illuminates the sample, the monochromator is used to convert the reflected or transmitted light to monochromatic signals for analysis. It is typically used in a spectrometer (or spectroradiometer) or a spectrophotometer.

There are different types of monochromator based on its color selection mechanisms and/or designs, e.g., prism, Czerny–Turner, holographic grating, double, etc. The principles of these monochromators are introduced in the “[Overview](#)” section below.

Overview

The main function of a monochromator is to separate the color components of a light. It can use either the optical dispersion phenomenon in a prism or that in a diffraction grating.

Figure 1 shows a scheme of a simple monochromator. Various types of monochromator have been developed, but a monochromator usually contains an entrance slit, an essential dispersing element, and a mechanism to direct the selected color to an exit slit for color selection purposes [1].

The Czerny–Turner monochromator is a type of monochromator using diffractive gratings as the dispersing element. A Czerny–Turner monochromator is sometimes referred to as a single monochromator because the radiant flux is only diffracted once [2]. A schematic diagram of a

Monochromator, Fig. 1 Scheme of a simple monochromator

Monochromator, Fig. 2 Basic structure of a Czerny–Turner monochromator

Monochromator, Fig. 3 An example of a prism monochromator

Czerny–Turner monochromator is shown in Fig. 2. In Fig. 2, the light under measurement (A) is incident through the entrance slit (B), reflected by a concave mirror (C) to become collimated. It then illuminates the optical grating (D), disperses light to different colors, reflected and focused by the concave mirror (E) to the exit slit (F). By rotating the optical grating (D), different colors of light can reach and exit at the exit slit (F), and such colors are “selected” by the monochromator. The orientation of the optical grating (D) and the spatial location of the exit slit (F) determine which wavelengths of the light are selected. The two concave mirrors (C and E) image the entrance slit on the exit plane. In practice, the collimating and focusing elements (C and E) are usually the same mirror, used twice [2].

The double monochromator usually contains two Czerny–Turner monochromators used in a system. Double monochromators are known for their double dispersion and thus can significantly reduce scattered light (Fig. 4) [2].

A prism monochromator uses a prism as the dispersing element (Fig. 3). It is not necessary for the collimating and focusing elements to be concave mirrors, but they can be optical lens. Usually, reflective mirrors are preferred over optical lens because mirrors conserve more optical radiation energy during the transmission process. However, because of the higher cost and small angular dispersion, prism monochromators are rarely made today (Fig. 4) [2].

A holographic grating monochromator uses holographically constructed concave gratings to simplify the optics. This eliminates some of the lenses and mirrors that would normally be

Monochromator, Fig. 4 Double monochromator

required with conventional flat plane grating monochromators.

When choosing a monochromator, the following specifications should be considered: wavelength range, wavelength accuracy, measurement speeds, spectral bandwidth, spectral scattering, slit widths, grating groove density (if applicable), mechanical and thermal stability, size and weight, stray light, and dispersion [3, 4]. For example, Table 1 shows the criteria for the selection of gratings according to the above specifications. The resolution is the minimum detectable difference

Monochromator, Table 1 The criteria for the selection of a grating [4]

Specification of monochromators	Criterion
<i>Groove density (or groove frequency):</i> The number of grooves contained on a grating surface (lines/mm)	Groove density affects the mechanical scanning range and the dispersion properties of a system. It is an important factor in determining the resolution capabilities of a monochromator. A higher groove density results in greater dispersion and a higher resolution Select a grating that delivers the required dispersion, such as that for a charge-coupled device (CCD), array detector, or a required resolution (with an appropriate slit width) when using a monochromator
<i>Mechanical scanning range:</i> The wavelength region in which an instrument can operate	Refers to the mechanical rotation capability (not the operating or optimal range) of a grating drive system with a specific grating installed Select a grating groove density that allows operation over the desired wavelength region
<i>Blaze wavelength:</i> The angle in which the grooves are formed with regard to the normal grating, often called the blaze angle	Diffraction grating efficiency plays an important role in spectrograph throughput. Efficiency at a particular wavelength is largely a function of the blaze wavelength if the grating is ruled, or a modulation if the grating is holographic Select a blaze wavelength that encompasses the total wavelength region of the applications. More attention should be paid to covering the short wavelength of the spectrum region
<i>Quantum wavelength range:</i> The wavelength region of highest efficiency for a particular grating	Normally determined by the blaze wavelength Select a grating with maximum efficiency over the required wavelength region for the applications

between two spectral peaks provided by a monochromator. Theoretically, resolution is approximately equal to slit width (mm) $\times$ dispersion (nm/mm), where the dispersion describes how well the light spectrum is spread over the focal plane of the exit slit. However, in practice, because

of aberrations in monochromators, the actual resolution is rarely equal to this. The actual resolution of a monochromator as a function of the slit width is described as the bandwidth (nm) of a monochromator.

When using a monochromator, some parameters need to be set up properly, as they affect the measurement results. For example, smaller slit widths produce smaller spectral bandwidths, which corresponds to a narrower spectral band at the exit slit (i.e., closer to the ideal single-wavelength output). However, smaller slit widths mean that less optical radiation power is transmitted through the monochromator, which results in lower output signals and decreases the signal-to-noise ratio of the signals measured. The bandwidth of commonly used monochromators is from the order of 10^{-2} to 10 nm. Detailed information on monochromators can be found in manufacturers' user manuals.

It is important to evaluate the performance of a monochromator to reduce measurement uncertainties (i.e., gain more confidence regarding the accuracy of the results measured). To evaluate the performance of a monochromator, the following characteristics should be considered: wavelength accuracy, spectral bandwidth, stray light, system reproducibility, and system linearity.

Definition

Arrangement of small fragments of stones, colored glasses, golden pieces, or other materials, fixed on walls or pavements and depicting an image or making an abstract pattern. The technique of mosaic is a decorative art that reached a peak during the Byzantine period of Christian art.

Overview

The traditional mosaics consist of marbles and stones in the scale of black and white (sometimes together with red) or other materials which were available in nature. At the beginning, in the Antique age, mosaics were used only as pavements, as stones on the ground, a floor material. During the first centuries of Christianity, during the Byzantine period, the Church took over the mosaic technique. The Byzantine technique with walls done with mosaics was new in the fifth and sixth centuries. In the basilicas of Ravenna, Italy, the Byzantine mosaic masters worked with entire walls of mosaic made up of small pieces of colored glass and gold, *tesserae*, affixed to mortar (Fig. 1). *Tesserae*, a term derived from a Greek word meaning “four-sided,” is the standard for mosaic pieces. Before being divided, the tesserae are part of a blown flat glass in the form of a “pizza plate” (in today’s terminology). *Smalti* is the technical term for the brilliant, opaque-colored crystalline material fused with glass.

In Turkey not least in Istanbul, we find the glass mosaic tradition from Antiquity and

Mosaics, Fig. 1 San Apollinare Nuovo (526), Ravenna. (Photograph by the author)

Byzantine times. Marble mosaic as a flooring material from the excavated parts of the late antique Great Palace is now in the Mozaik Müzesi in Sultanahmet (Fig. 2). The Byzantine style, with large amounts of glass mosaics, can be seen in the Hagia Sophia (ninth to thirteenth centuries) (Fig. 3), Chora/Kariye Museum and Pammakaristos Church/Fethiye Museum (both fourteenth century), decorated entirely on walls and ceilings, and in apses and domes.

The new materials that the Byzantine mosaic masters introduced were colored glass and gold. These materials offer a wider and more intense color scale than the marble mosaics. The tesserae-mosaic is a kind of color material that is mixed optically (on the retina of the eye). The material interacts in a special way with vision and light. The surface is shiny, hard, and reflective. Glass pieces are shiny and slightly irregular in pure colors and gold. The gold picks up light and reflects gold light back into the room. The entire composition involved the setting of mosaic pieces at different

Mosaics, Fig. 2 Great Palace (fifth century), Istanbul. (Photograph by the author)

Mosaics, Fig. 3 Hagia Sophia (thirteenth century), Istanbul. (Photograph by the author)

angles so as to reflect light as effectively as possible. Seen from a distance, the singular mosaic pieces appear to model figurative forms. In the present time, this technique is considered as somewhat comparable to the compositions of the Neo-impressionist painters of the 1880s. Thus, the mosaic masters possessed knowledge of the eye's

ability to apprehend color mixing. They also acquired understanding of the changes colors underwent with distance and also of the interaction of light and material.

The images in the Byzantine basilicas are often constructed from contrasting colors. Red stands against green in costumes and clothing designs. A pair of red shoes usually meets green grass. When two contrasting colors meet, there is an increase in both colors. Another approach in the sixth century, used by the mosaic masters to avoid changes in color, was to apply a contour line between two colors. This contour line prevents the colors from spilling over into each other. Instead, the colors are depicted without visible distortion. The gold mosaic primarily represented the halos of the holy figures but was also placed in the background. The subject of the church mosaics was to serve the spirit, not the body. In the images, all suggestions of movement have been avoided; instead, an "eternal existence" is shown. The combined effect in the milieu of the church is a glittering, multicolored immaterial curtain. The material, the light, and the surface interact.

By studying the mosaics, it is possible to see how the mosaic masters applied the tessera pieces with skill and knowledge of color and what happens optically at a distance. The mosaic masters mixed colors optically for entire large areas of color. For instance, in order to give a lawn its various shades of green and thus get a nuanced and living surface, the mosaic pieces were placed against each other in turquoise, green, and gray-green for the purpose of combining and so forming the greenness of the grass. Gold mosaic was also used – in addition to create areas of gold color and point out important details – to mix the colors in larger fields.

When viewing a mosaic wall, the changes of the material from matte to shiny can be discerned. How the mosaic is reflected depends on its angle against the wall. Two pieces of the same inherent color placed with different tilt angles result in that each one will have a different appearance. This effect results from light projecting and reflecting different information to the eye. Reflection is also dependent on how the light strikes the mosaic pieces, on whether the tesserae are made of glass (shiny) or marble (often matte), on the viewing

Mosaics, Fig. 4 The Golden Hall, Stockholm City Hall (1923). (Photograph by the author)

angle, and on how the viewer moves in the room. No movement of the subjects or the motifs on the walls is discernible. The hues are perceived as stable and unchangeable, and unaffected by nearby colors. But with the movement of the viewer in the room, and the changes in the eye's view, the mosaic walls are transformed from matte to shiny, and back again. Through the mosaic, the viewer participates in the process of change.

In the present time, it is possible to find the impact of late Antique mosaics in Sweden, for example. In 1919, the Swedish artist Einar Forseth made a study trip to Italy. The architect Ragnar Östberg designed the Stockholm City Hall in 1923, and Einar Forseth was appointed to create the Golden Hall, one of the main lounges for dining and gathering in the edifice. Forseth chose mosaic for his commission. The Golden Hall is thus covered with more than 18 million glass and gold mosaic pieces (Fig. 4). The mosaics depict Swedish

historical figures and interpret certain events in the Swedish history, but the technique, the imaging, and the colors are in Byzantine style with its origins in Ravenna. Besides the Stockholm City Hall, the Byzantine technique can be seen in an underground station situated in Rinkeby, a suburb of Stockholm. In his adomment from 1975, the artist Nisse Zetterberg used mosaic in gold, in the tesserae technique, applied with different angles to the background. The mosaics depict patterns, symbols, and runes inspired by the Viking age, once found in the Rinkeby excavations.

Motion and Color Cognition

Donald Hoffman

Department of Cognitive Sciences, University of California at Irvine, Irvine, CA, USA

Synonyms

Achromatopsia; Color from motion; Dynamic color spreading; Neon color spreading

Definition

Motion and color cognition is a branch of cognitive neuroscience devoted to using brain imaging, psychophysical experiments, and computational modeling to understand the interactions between motion and color processing in the human visual system.

Overview

The relationships between the perceptions of color and visual motion are complex and intriguing. Evidence from patients with certain rare forms of damage to the cerebral cortex indicates that color and motion are to some extent processed separately within the visual system. This conclusion is buttressed by physiological evidence for separate neural pathways for the processing of color and motion and psychophysical evidence that the perception of motion in color displays is greatly reduced when the colors are isoluminant. However, experiments and demonstrations reveal that the perceptions of color and motion can interact. Motion can trigger the perception of color in achromatic stimuli and in uncolored regions of space. Color can determine the perceived direction of motion, and changes in color can trigger the perception of apparent motion. This article briefly reviews the evidence for separate processing of color and visual motion and for the ways they interact.

Evidence for Separate Processing of Color and Motion

Patients with the rare condition of *cerebral achromatopsia* cannot perceive colors, due to damage of cortex in the inferior temporal lobe of both cerebral hemispheres [1, 2]. Cerebral achromatopsia differs from the more common condition of color blindness, in which one or more of the normal three cone systems in the retinas are missing. A color-blind person missing the long-wavelength cone system, for instance, can still perceive many colors but has a range of color perceptions more limited than that of a normal trichromat, who has all three cone systems. Cerebral achromatopsics can have all three cones systems intact in their retinas but are still unable to perceive any colors because of damage to visual cortex. Yet many cerebral achromatopsics have no difficulty perceiving visual motion, indicating that the processing of color within the human visual system can be damaged without also damaging the processing of visual motion. (See also the Encyclopedia of Color Science and Technology entry on color naming and categorization in inherited color deficiencies and the entry on color perception and environmental impairments.)

Conversely, patients with the rare condition of *cerebral akinetopsia* cannot perceive motion, due to damage of cortex in the middle temporal area of both cerebral hemispheres [2, 3]. According to Josef Zihl and his colleagues, one such patient “. . . had difficulty, for example, in pouring tea or coffee into a cup because the fluid appeared to be frozen, like a glacier. In addition, she could not stop pouring at the right time since she was unable to perceive the movement in the cup (or a pot) when the fluid rose” [2, 4]. Yet this patient was able to perceive color, indicating that the processing of motion within the human visual system can be damaged without also damaging the processing of color.

Cerebral achromatopsia and cerebral akinetopsia indicate that color and motion are to some extent processed separately within the visual system. Further evidence for their separate processing comes from neuroanatomical and neurophysiological studies revealing that the visual

system has a parvocellular pathway that processes color and detailed form information and a magnocellular pathway that processes motion, depth, and coarse form information [5]. These pathways are clearly segregated in the lateral geniculate nucleus of the thalamus, a relay station for visual information traveling from the eyes to visual cortex. One psychophysical correlate of this separate processing is the observation that perceived motion in color displays is greatly reduced when the displays are made isoluminant, an effect first discovered in 1911 by Pleikart Stumpf [6].

Evidence for Interactions in the Processing of Color and Motion

However, despite the anatomical, neuropsychological, and psychophysical evidence for the

Motion and Color Cognition, Fig. 1 Benham's top. Spinning this achromatic pattern leads to perceived colors

Motion and Color Cognition, Fig. 2 Color and motion correspondence. This figure depicts four frames of a movie in which the colored blocks could, in principle, be

perceived either as moving to the left or as moving to the right. Color information, even at isoluminance, biases us to see movement to the right

separate processing of motion and color, there are several intriguing visual phenomena which clearly demonstrate that the perception of motion and color can interact. An early example was discovered by the French monk Benedict Prevost in 1826, when he noticed that if he waved his hands in the dim light of the cloisters, then colors appeared near his moving fingers [7].

Charles Benham marketed a top in 1895 with a pattern similar to that shown in Fig. 1 [8]. Spinning the top leads to the perception of the colors of an artificial spectrum, again demonstrating an interaction between color and motion. (See also the Encyclopedia of Color Science and Technology entry on illusory colors.)

Karen Dobkins and Tom Albright discovered in 1993 that color can influence the perceived direction of motion [2]. They showed subjects a movie in which a row of red and green blocks appeared to move horizontally. Four frames from such a movie are shown schematically in Fig. 2. From one frame to the next, the blocks moved exactly one half of a block width, so that the movie is compatible, in principle, with being seen as blocks moving to the left or to the right. However, if the brightness of the green blocks differs from that of the red blocks, then the visual system sees a direction of motion consistent with this, i.e., such that the brightness of each block does not appear to change as it moves. However, if all the blocks are equal in perceived brightness, the visual system sees a direction of motion consistent with the colors, i.e., such that the color of each block does not appear to change as it moves. Thus, color information by itself, apart from luminance information, can influence the perceived

direction of motion. Similar evidence for the interaction of color and motion comes from experiments showing that color can affect the perceived direction of discrete apparent motion stimuli [9] and of sine-wave gratings [10, 11].

Conversely, V.S. Ramachandran discovered in 1987 that motion can “capture” color borders. If an illusory contour or a group of random dots are moved in the vicinity of a color border, then that border appears to move in the same direction as the illusory contour or random dots [12].

Motion and Color Cognition, Fig. 3 Wallach’s display. The *red neon* color spreading seen in the upper half of the *square* becomes more pronounced when the *lines* are moved *horizontally*, but appear to be moving *vertically*

Hans Wallach in 1935 created a display similar to that shown in Fig. 3 [13]. As can be seen in the figure, the oblique lines are red in the upper half of the display and black in the lower half. The red color of the lines in the upper half appears to spread faintly through the white regions, a phenomenon known as neon color spreading.

Wallach then put the oblique lines in motion, translating them sideways underneath a rectangular window, indicated in Fig. 3 by a gray frame. This leads to a bistable perception of the motion of the lines. Sometimes observers see them translating horizontally, as in fact they are. But sometimes, due to the ambiguities of motion seen through small apertures, observers see the lines translating vertically. In this latter case, observers report that the red neon color spreading is greatly enhanced. Thus motion can interact with color by enhancing neon color spreading.

A similar interaction between color and motion can be seen in displays of dynamic color spreading [2, 14]. Two frames from such a display are shown in Fig. 4. Each frame has a few hundred dots, which do not change position from frame to frame. Some of the dots are colored red and others, within a circular region, are colored green. The circular region in which dots are colored green moves slightly from frame to frame. This leads to the perception of a glowing green

Motion and Color Cognition, Fig. 4 Two frames from a movie display of dynamic color spreading. These frames can be stereo fused to get an impression of a glowing *green* disk hovering over a field of *red* dots

Motion and Color Cognition, Fig. 5 Dynamic color spreading seen amodally. The *red dots* appear to be holes in a sheet of paper, and through the holes one sees a *green* disk moving over a *red* background

disk that moves over a field of static red dots. One can get feel for the perception of the glowing disk by using Fig. 4 as a stereo display, and cross fusing the two images. One sees a glowing green disk floating in front of the field of red dots.

Sometimes the green disk does not appear to float in front of a field of red dots. Instead, the red dots appear to be holes in a white sheet of paper, and through the holes one sees a solid green disk moving over a uniformly colored red background. This “amodal” perception of dynamic color spreading is illustrated in Fig. 5. One can get a feel for this amodal perception by again treating Fig. 4 as a stereo display, but this time fusing the two images by diverging the eyes rather than crossing them.

Displays of dynamic color spreading demonstrate that apparent motion can trigger the creation of illusory objects and the spreading of color over the surfaces of such illusory objects. The surface color can have a neon quality if the object is seen floating in front of the dots or a paint quality if the object is seen amodally.

Summary

Evidence from neuropsychology, neurophysiology, and psychophysics indicates that color and motion are to some extent processed in separate

pathways of the visual system, but that these visual pathways interact in a sophisticated fashion, and that together they can create the appearance of objects in motion with colored surfaces.

Munsell, Albert Henry

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Munsell was born on January 6, 1858, in Boston, MA, where his father was in the piano business. After high school he attended the Massachusetts Normal Art School in Boston. In 1879 he studied Ogden Nicholas Rood's influential book *Modern Chromatics*. In 1881 he was named an instructor and later a lecturer at this school, positions he held for 25 years. He was awarded a scholarship that made it possible for him to study from 1885 to 1888 at the Académie Julian and the École nationale supérieure des Beaux-Arts in Paris and 1 year in Rome. After he returned he was an active painter of portraits and seascapes. In 1889 he received a patent for an adjustable artist's easel. In 1894 he married Julia Orr, the daughter of a New York financier, with whom he had a son,

Albert Ector Orr Munsell, and three daughters. Munsell died on July 28, 1918, in Brookline, MA [1].

M

Major Accomplishments/Contributions

As a lecturer at the art school, Munsell became concerned with how to teach students about colors in a meaningful manner. In 1899 he developed a model of a balanced color sphere that, when spun rapidly, resulted in a gray appearance, thus showing a kind of color balance. He received a patent for it in 1900 [2]. Munsell met O. N. Rood, then professor of physics in New York, in 1899 showing him his color sphere, with Rood commenting positively on it. Simultaneously, Munsell concerned himself with the design of the interior of the color sphere. In April 1900 he sketched a hue circle based on the decimal system, with five primary, five secondary, and ten intermediate hues. It continues to be the basis of the modern system. Munsell, from his studies in painting, had a clear idea of lightness or value, as it was typically called in painters' circles. In 1901 he

Munsell, Albert Henry,
Fig. 1 Munsell's
 schematic depiction of the
 color tree

obtained a patent for a photometer he called a luminometer. It was manufactured in small numbers in the following years [3]. The basic question of using a logarithmic or a power root scale to relate the physical data of the luminometer to perceived lightness in his system was a question not fully resolved until after Munsell's death. In 1902 Munsell hand-plotted color intensity and lightness data for different pigments, earlier established by W. Abney, and realized that a sphere was an incomplete representation of perceived colors. As a result he began to name his color solid a "color tree." Having established a hue circle and a subjective lightness scale, he was aware that for completeness he needed to define a chromatic intensity scale. It is not established how he arrived at the term "chroma" for that purpose. In March 1902 he sketched a color solid based on the three attributes as shown in more detail in Fig. 1 (Ref. 4, 1907). Samples were to be spaced according to perceptual equal differences by parameter. Munsell began to establish such samples to fill limited hue pages. Munsell described the system in *A Color Notation*, first published in 1905 [5]. A first edition of the *Atlas of the Munsell Color System* was published in 1907 containing eight charts of painted samples of ten different hues [6]. In the 1915 edition of the atlas, the number of samples was doubled. Munsell also introduced artist's tools based on his system: Munsell crayons and Munsell

water colors. As a painter Munsell was interested in color harmony, and he established nine principles based on his color solid [7].

Throughout the development of the system, he consulted with a broad group of scientists and artists and gave many presentations in the USA and in Europe. In 1917 he formed the Munsell Color Company to operate the business of producing the atlas. After his passing it was taken over by his son A. E. O. Munsell and other stockholders. At about the same time, the National Bureau of Standards began to show interest in the system and supported sample measurement and expansion of the system. An enlarged edition with 20 hues was published in 1929 [8]. In the 1940s extensive experiments were made under the auspices of the Optical Society of America resulting in the Munsell Renotations (for Munsell system colorimetric renotation data, see, e.g., Ref. [9]), colorimetric definitions of a revised version of samples of the atlas that continue to be the basis of the modern system. Munsell's is perhaps the most important color atlas system yet developed.

Neo-impressionism

Georges Roque
Paris, France

Definition

Neo-impressionism is an artistic movement coming after Impressionism. It started as a section of the eighth and last Impressionist Exhibition in 1886. Its founding figure was Georges Seurat (1859–1891), whose monumental painting, *A Sunday on the Grande Jatte*, reworked for its presentation in the 1886 exhibition, is a kind of standard bearer of the whole movement. Seurat died in 1891 at his early thirties. His death corresponds more or less to the end of Neo-impressionism first life, all the more since Camille Pissarro gave up the new technique around the same period. After Seurat's death, Paul Signac (1863–1935) became the leader of the movement and his chief publicist. At the beginning of the

Georges Roque has retired.

twentieth century, Neo-impressionism had a revival during the Fauve period; most of the pioneers of abstract art also had a Neo-impressionist phase in their way to abstraction. The main features of Neo-impressionism are a faith in science and color science and the use of bright colors and of a special technique (optical mixture) aimed at giving more luminosity to colors; this technique, which implies a mechanical application of the brushstroke, was also intended to suppress the skill of the hand as characteristics of the individualism dear to the Impressionists.

Overview

The term “Neo-impressionism” was coined by the critic Félix Fénéon, who was the earliest and one of the best spokesmen of the movement. The Neo-impressionist artists did not want to break with the Impressionists (one of them, Camille Pissarro, was himself one of the leading Impressionist painters) but continue it in a more rigorous and scientific way. However, one of the differences between the two movements is that, unlike the Impressionists, the Neo-impressionists wanted to render permanent features and not ever-changing moments. A superficial characteristic of their brushstroke is the use of small dots of color, hence the term of pointillism in order to describe their technique.

The main firsthand sources of information to understand Neo-impressionism are (a) an unpublished letter of Seurat to Maurice Beaubourg (1890) of which different drafts are known ([1], pp. 113–114), (b) a letter of Pissarro to his dealer Durand-Ruel (1886) ([1], pp. 54–55), (c) the book written by Signac in order to champion the movement (1899) [2], and (d) an article written by the critic Félix Fénéon and based on information provided by the artists (1886) ([1], pp. 108–110); this article is sometimes considered as the Neo-impressionist manifesto.

Art and Science

According to these writings, the main sources for Neo-impressionist color practice are Michel

Eugène Chevreul [3], basically known through Charles Blanc [4], and Ogden Rood [5]. Now these sources are contradictory, at least concerning color harmony, as Chevreul used pairs of complementary colors popularized through Blanc’s color star (Fig. 1), while Rood used new pairs of complementary colors based on Helmholtz’s researches (Fig. 2). This explains Seurat’s hesitation between the two color systems.

The Neo-impressionists used scientific sources and were very interested in what science could bring them; for this reason, they visited Chevreul on one occasion and his assistant on another, in order to understand better the “division of light” (on the importance of Chevreul for them, see [6], pp. 350–377). Their interest for color science raises the issue of whether or not they had a scientific approach to color. This is a very debated topic, as answers have been completely opposed: some specialists think Seurat and his fellow painters used a “scientific” method based on color science; on the contrary, others consider that the Neo-impressionist artists misunderstood the scientists’ advices, so that their practice was pseudo-science. Why are there so different positions? It depends on the (implicit or explicit) conception of the relationship between art and science that frames the specialists’ thinking. For those who want to bridge the gap between art and science, Seurat’s practice is obviously applied science. Conversely, those who hold that science remains out of the scope of artists will emphasize the gap between scientific data and artistic practice and will insist accordingly on the artists’ misunderstanding of science. In order to avoid these difficulties, the distinction between color science and color theory might prove useful ([6], pp. 12–17; [7], pp. 44–46). Their function, indeed, is different: color science is a set of experiments and principles aiming at understanding chromatic phenomena and expressing their properties, while color theory is a set of principles, doctrines, rules, and formulas directed at artists and suggesting recipes for choosing, preparing, organizing, and matching colors on the canvas. From this point of view, the difference between an artistic and a scientific approach to color can be more easily understood. For example, Chevreul had

Neo-impressionism,

Fig. 1 *Color star* from Charles Blanc, *Grammaire des arts du dessin*, 1867

Neo-impressionism, Fig. 2 Rood's color wheel, 1879

noticed that two areas of complementary colors tend to enhance each other when juxtaposed ([3], § 237), but he never recommended this effect to be deployed in painting, despite what is usually assumed. In fact, for him, the enhancing effect was not especially desirable. However, for painters preoccupied with luminosity and saturation,

enhancing colors by the juxtaposition of complementary hues soon became an excellent recipe. Examples like this show that “misunderstanding” science is not a mistake that can be avoided by the better-informed artist, but is instead the inescapable result of a difference of aims between the painter and the color scientist.

Optical Mixture

Different origins of the so-called pointillism can be traced from the sources given by the artists. The first is Charles Blanc, who coined the expression “optical mixture,” a technique already used by Delacroix, according to him, as well as by the Impressionists. The basic idea is to mix colors not on the palette, but juxtapose them on the canvas, so that when seen at a distance, they fuse into the eye and produce a new color not present at such on the canvas. As Blanc put it:

If at a distance of some steps, we look at a cashmere shawl, we generally perceive tones that are not in the fabric, but which compose themselves at the back of our eye by the effect of reciprocal reactions of one tone upon another. Two colors in juxtaposition or superposed in such or such proportions, that

Neo-impressionism,

Fig. 3 Drawing from Charles Blanc's *Grammaire des arts du dessin*, 1867

is to say according to the extent each shall occupy, will form a third color that our eye will perceive at a distance, without having been written by weaver or painter. This third color is a resultant that the artist foresaw and which is born of optical mixture. ([4], p. 475)

In order to make his suggestions more concrete, he added a drawing of little dots (Fig. 3, left) or little stars (Fig. 3, right) on a uniform ground: "A similar phenomenon will be produced upon a yellow stuff starred with violet and upon a blue stuff sown with orange spots" ([4], p. 475).

A physicist, Ogden Rood, gave a more complete description of optical mixture in his book published in 1879 and translated into French in 1881. He first described a method given by Mile in 1838 in order to mix colors in the eye from small contiguous dots of colors ([5], p. 140). Rood also quoted John Ruskin, who recommended a similar method ([5], p. 140). It must be noted that Monet as well as Signac praised a lot Ruskin's book *The Elements of Drawing*.

Rood himself gave painters the same advice:

There is, however, another lower degree of gradation which has a peculiar charm of its own, and is very precious in art and nature. The effect referred to take place when different colours are placed side by side in lines or dots, and when viewed at such a distance that the blending is more or less accomplished by the eye of the beholder. Under these circumstances the tints mix on the retina, and produce new colours, which are identical with those which are obtained by the method of revolving disks. ([5], pp. 279–280)

Neo-impressionism, Fig. 4 Drawing of experiment from Rood's *Modern Chromatics*, 1879

Luminosity

The end of the quote explains why the Neo-impressionists were so interested by the method suggested by Rood (after Blanc and Ruskin): Rood made a fascinating experiment in order to compare the luminosity of colors mixed on the palette with the optical mixture of the same hues. For this purpose, he used two rotating disks. The larger disk was divided into two equal halves, painted with vermilion in the upper part and ultra-marine blue in the lower part (Fig. 4).

Neo-impressionism,

Fig. 5 Compared result of color mixtures, Rood's *Modern Chromatics*, 1879

Mixture on Palette.	Mixture by Rotation.
50 violet + 50 Hooker's green..	= { 21 violet + 22.5 Hooker's green + 4 vermilion + 52.5 black.
50 violet + 50 gamboge.....	= 54 violet + 20 gamboge + 26 black.
50 violet + 50 green.....	= 50 violet + 18 green + 32 black.
50 violet + 50 Prussian-blue...	= 47 violet + 49 Prussian-blue + 4 black.

Now, an equal number of drops of the same washes of watercolor pigments were mixed on the palette in order to paint the small disk with this mixture. After rotating the two disks, Rood realized that the smaller disk looked gray and dull, while the larger one looked brighter. So, in order to obtain a similar result on both disks, he had to add black to the larger one. But the surprising result of the experiment is that Rood had to add up to 52% of black to the larger disk in order to match the mixture made on the palette (Fig. 5).

Many artists were struck by this experiment, and Fénéon gave it as an example in order to explain the new technique and its superiority in terms of luminosity. Quoting the results of Rood's experiment, Fénéon stressed that "the luminosity of optical mixtures is always superior to that of material mixture" ([1], p. 109) and justified accordingly the new Neo-impressionist technique.

However, the theory of "optical mixture," as understood by painters, when suggesting that it should be possible to get an additive-like mixture by juxtaposing pigments so that they mix in the eye instead of physically, has been a source of enduring confusion. The point that often eluded painters is that this type of optical mixture does not add together the luminous energies of the individual colors; it merely averages them. Furthermore, there is a contradiction in the theory, when painters wished to combine the two principles: complementary colors and optical mixture. In principle, both have in common to heighten colors: they heighten hues in the case of juxtaposing complementary colors; they heighten luminosity in the case of optical mixture. However, painters were not aware of the fact that both principles correspond to two different laws of perception. The color contrast only functions if the samples of color are big enough. For when the juxtaposed zones are thin, what happens is exactly the opposite: instead of enhancing each other, that

is, to exaggerate their difference, they tend to "assimilate," that is, to produce visually a dirty gray.

This leads to a puzzling conclusion: if juxtaposing dots of complementary colors, as the Neo-impressionist painters did, does not give the paintings more luminosity, how could the great luminosity of their paintings be explained? The answer has been given by Robert Herbert, the scholar most familiar with Neo-impressionism. As he explained, if the Neo-impressionist paintings are indeed very luminous, it is because the optical mixture does not work, that is, that the dots are big enough to be still perceived at the normal distance at which we look at the paintings! And it is precisely because the dots do not mix in order to produce new hues that they keep their luminosity ([8], p. 19). It is not the case to stress here that the painters were "wrong" in their use of theory, but only to understand that they were so fascinated by the possibility of obtaining a luminosity similar to that of color-light that they forgot scientists' warnings against the danger of confusing pigments and light colors.

This means that the numerous misunderstandings arising from the notion of optical mixture are inevitable since they are due to the very ambiguity of the concept, which suggests a strong analogy between light and the eye, as opposed to pigment mixture. However, painters work with pigments and not with light but were eager to obtain through their pigments a luminosity similar to that of additive mixture. Hence, the opposition in Signac's writings between mixtures on the palette he considered disgusting and optical mixture "purity."

The Neo-impressionist technique is then rather complex and cannot be limited to "pointillism." The term "pointillism" is often considered as a synonym of Neo-impressionism but is not. Signac insisted a lot on the fact that the dots are just a means and cannot be considered as a characteristic of Neo-impressionism: far more important for

its technique is the “divided touch.” As the painter wrote: “*Division* is a complex system of harmony, an aesthetics rather than a technique. The *dot* is only a means. To divide is to seek the power and harmony of color, through representing colored light by its pure elements and by using the optical mixture of these pure elements, separated and proportioned according to the essential laws of contrast and gradation” ([1], p. 121).

Harmony

As results from this quote, the idea of harmony in Neo-impressionism goes beyond color, due to the Neo-impressionists’ adherence to symbolism. In his letter to Beaubourg in which he explained his main aesthetic ideas, Seurat also related harmony with tones and lines ([1], pp. 113–14). The idea of color harmony must also be associated with the concept of harmony in anarchism, whose ideals were shared by several of the painters. For the anarchists, indeed, the idea of harmony makes it possible to reconcile the individualism characteristic of the movement with collective life. Similarly, a parallel can be drawn between the individuality of colors and the painting as a whole, as all the single elements used (dots) interact with each other and contribute to the general harmony of the painting [9].

Neo-impressionism and Color Development in Twentieth-Century Art

It is striking to note that most of the painters that counted for the development of color in the first half of the twentieth century passed through a Neo-impressionist period. The list is quite impressive: Matisse, Mondrian, Kandinsky, Malevich, Braque, Delaunay, Kupka, and so on. This raises the question of why Neo-impressionism was so important for the development of the practice of color in painting.

The first feature to be noted is the extraordinary homogeneity of the pictorial matter: the dots that serve to render nature are the same as used for a human body. And even in the human body, no

difference is made between hair, skin, clothes, and so on. Everything is treated in the same way; besides color, this is also true for lines and spaces. This homogeneity is important for several reasons. First, it means the rejection of the skill of the hand as an expressive device. For the Neo-impressionists, what matters are the scientific bases of the technique. Furthermore, through the homogeneous construction of the surface, the touch becomes independent of the objects represented on a painting, since the same kind of dot is used on the whole surface of the canvas. From this point of view, the Neo-impressionists have emphasized special means, which are artificial devices that do not resemble nature.

Yet the fact of using artificial means has another consequence: the touch (as a means) becomes independent of the representation of nature, which was the traditional aim of painting. Finally, not only is the divided touch a technique in order to paint through color only, but it also contains a syntax, that is, a way of organizing the contiguous color dots, as well as a complex harmony system. The vocabulary (the dots), the syntax (the divided touch), and the harmony constitute a totality in itself, independently of the world of the objects the painting is supposed to represent. This is the main reason why the next generations of painters were so interested in Neo-impressionism, read avidly Signac’s book, and had a Neo-impressionist phase: the dots were a way of exploring the possibility of painting through colors only, which eventually led to abstract art [10].

Summing up, it must be emphasized that a lot has been written on Neo-impressionism. On color in particular, the interested reader can also refer to G. Roque [7], J. Gage [11], and P. Smith [12], who have developed different aspects related to Seurat, and G. Roque [13], who refers to Signac and color theory.

Neon Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Glow discharge lamps](#); [Low-pressure glow discharge lamps](#)

Definition

Lamps that produce light as a result of an electrical glow discharge, generated between two electrodes, in a low-pressure neon, argon, krypton, helium, xenon, or carbon dioxide vapor, which is contained in a transparent bulb or tube.

Note that also glow discharge lamps using no neon but one of the other vapors mentioned in the definition are referred to as neon lamps.

Neon lamps are usually not used for general lighting purposes, and therefore only the fundamentals of their working principle and of their properties are described in this encyclopedia.

Working Principle of Glow Discharge Lamps

In a glow discharge, the electrons taking part in the initial discharge are made free by external sources like thermal collisions between atoms, ultraviolet, or cosmic radiation. In a discharge bulb or tube with gas at very low pressure and a voltage of several hundred volts applied across cold electrodes, the electrodes made free by the external sources move at high speed toward the anode and ionize some gas atoms creating positively charged ions and more free electrons. Some

of the positive ions hit the cathode at high speed, thanks to the low pressure of the gas of less than 0.05 atmosphere. They release by their impact-free electrons from the cathode surface. Electron production is thus not by external means like heated cathodes but by secondary emission as a result of positive ions hitting the cathode surface. Atoms can also be excited to a higher energy state by the moving electrons and ions, and in releasing the extra energy so obtained, photons are created that are responsible for the typical soft and transparent luminous glow. The color characteristics of the glow light are dependent on the type of gas used.

The glow discharge process is only stable at small current densities in the order of milliamperes. By increasing the voltage, the current is increased, and the process will change into that of an arc discharge that is typical for most discharge lamps used for lighting: low- and high-pressure sodium, mercury, and metal-halide lamps. Some arc discharge lamps make use of the glow light process to facilitate ignition of the lamp (the red neon glow light of a starting low-pressure sodium lamp). Glow light starters (used in some fluorescent lamp systems) also make use of this process.

Tubular Glow Discharge Lamps

Tubular neon lamps can be shaped into any form and produced in many different color versions. They are therefore particularly well suited for advertising signs. LED strings now offer an alternative. Tubular neon signs are also popular in decorative art.

Construction

Lead glass is usually used for the tube because it can easily be bent and fused. Sometimes red- or yellow-tinted glass is used to adapt the original color of the glow light. Yellow-tinted glass will, for example, change the color of blue glow light into green.

The length of the tube usually is less than 2 m, and its diameter varies between some 7 and 35 mm. Larger signs are constructed from various pieces of individual tubes.

The electrodes are large rings of pure iron with a diameter of 15–20 mm and a length of about 80 mm.

Pure neon as fill gas results in red light; most other colors can be produced with argon-mercury mixtures. Helium results in warm white light.

Fluorescent powders on the inner wall are often used to extend the range of colors or to improve light output.

Properties

System Luminous Efficacy

The luminous efficacy of clear glass tubes is low with some 5 lm/W. Fluorescent-covered tubes have efficacies depending on the color between some 10 lm/W for red, 30 lm/W for blue, more than 80 lm/W for green, and 75 lm/W for white. The values vary quite a bit with the type of fluorescent powder used.

Lumen Package Range

The luminous flux of neon tubes is expressed in lumen per meter of tube length. Values vary according to the type of gas, type of fluorescent powder (and thus color), lamp current, and tube diameter between 100 lm/m (clear glass neon-filled) and 1600 lm/m (fluorescent-coated tube producing green light).

Color Characteristics

Applying different fill gasses, different tinted glass tubes, and different fluorescent powders enable the production of all the colors of the spectrum.

Lamp Life

Neon tubes have electrically a very long life. Their practical life is often indicated as the time after which the light output has dropped to 50%: 10,000–20,000 h.

Run-Up and Reignition

Ignition of the cold lamp is instantaneous, and hot reignition is immediate as well. This makes it possible to produce flashing neon sign installations.

Compact Glow Discharge Lamps

Neon compact glow lamps were used as indicator lamps on all kinds of electrical and electronic equipment. LED signal lamps have taken over this application. They were also, and still are, used for low-level lighting in night lamps in children's and hospital bedrooms and corridors. Also, here LEDs are an alternative. The lamp's electrodes can be shaped in many different forms so that the glow light can be used to display letters, numbers, and symbols. By making the lamp flashing, a flickering neon glow, for example, in the form of a candle, flame can be produced.

Construction

Compact glow discharge lamps consist of a compact glass bulb with two electrodes closely positioned together. The nickel or iron electrodes can take any form like strip, disk, ring, cross, etc. The filling gas usually is neon giving an orange-red glow. Fluorescent coating is used for green-emitting lamps. Miniature indicator lamps in sizes from some 5 to 15 mm operate on a current of 0.5–1 mA. The operating current of the larger types in the size of an incandescent bulb goes up to 50 mA.

Properties

System Luminous Efficacy

Luminous efficacy is 0.3–1 lm/W, which for indicator lamps is reasonable enough.

Lumen Package

The lumen output, less to much less than one lumen, is low but for indicator lamp applications sufficient.

Color Characteristics

Clear glass bulbs produce orange-red light. With fluorescent coating of the bulb, many more colors can be produced, especially also green, which for indicator lamps is indispensable.

Lamp Life

Lamp life is 10,000–100,000 h.

Run-Up and Reignition

Cold start and reignition are both instantaneous, which of course for indicator lamps is the first requirement.

Newton, (Sir) Isaac

Renzo Shamey

Color Science and Imaging Laboratory, College of Textiles, North Carolina State University, Raleigh, NC, USA

1642/1643–1726/1727 (The difference is due to the use and report of the date in two calendars: Julian and Gregorian. According to the Gregorian calendar, the date of Newton's birth was 4 Jan, 1643 and that of his death 31 March 1727) (Portrait of Isaac Newton in 1689 (age 46) by Godfrey Kneller, Wikimedia)

Biography

Isaac Newton was an English physicist and mathematician, who made seminal contributions to several domains of science, and was considered a leading scientist of his era and one of the most influential scientists of all time. He was born prematurely on 25 December 1642 in Lincolnshire, England, of Hannah Ayscough and Isaac Newton (father) [1]. His father passed away before he was born. His mother remarried when he was 3 years old and he was left in the care of his grandmother, a situation he resented.

He attended the King's School in Grantham where he learned Latin among other things until the age of 17. In 1661, he was admitted to Trinity College, Cambridge, and was educated in Aristotelian philosophy. However, Newton also read the works of Descartes, Galileo, and Kepler. In 1665/1666 he spent most of the time at his ancestral place in Lincolnshire because of the dangerous spread of plague in Cambridge. During that time he did most of his experimental work with glass prisms and much of his mental work that resulted in the publication of *Principia* in 1687.

In 1667 he returned to Cambridge and became a fellow of the College of the Holy and Undivided Trinity [2, 3]. In 1669, and at the age of 26, Newton became the Lucasian professor of mathematics. According to his secretary Humphrey Newton (no relation), his lectures were often poorly attended and few understood him and that sometimes he read to the walls [4]. Newton occasionally traveled to London to attend the Royal Society lectures and was named a fellow in 1672. He became its president from 1703 to 1727. Newton was given various levels of support by the Royal Society. His interpretation of the optical experiments was strongly disputed by Robert Hooke, an employee of the society since 1664, as a result of which he published his book *Opticks* only in 1704, after Hooke's death. He was supported by the society in his bitter and controversial dispute with the German polymath and philosopher Gottfried Wilhelm Leibniz over who had developed calculus first [Leibniz's notations are used today].

Newton also dwelt in politics and was a member of the House of Commons between 1689 and 1690 and then again from 1701 to 1702. In 1705 he was knighted by Queen Anne during her visit to Trinity College. He held two government offices: first he was the Warden of the Mint from 1696 to 1700 and then Master of the Mint from 1700 until his death in 1727. At the time of Newton's funeral, the French philosopher Voltaire who was in England compared Newton to Descartes and said of Newton that "he was never sensible to any passion, [and] was not subject to the common frailties of mankind, nor had any commerce with women" [5]. Newton had strong opinions on religion and wrote a number of works, not published during his lifetime, that would have then been considered heretic in that period. Newton never married and died intestate in Kensington, London, when his relatives quarreled over the division of his considerable estate. He is buried in Westminster Abbey in London, England.

Major Accomplishments/Contributions

Newton's Theory of Color

Arguably our modern understanding of light and color begins with Newton's discovery of light dispersion which he published in 1672. In the late 1660s, Newton started experimenting with the phenomenon of colors and lectured on optics [6]. At the time, it was generally thought that colors were mixtures of light and darkness. It was also believed that prisms imparted colors to light. Through observation of light refraction, Newton realized that this theory was incorrect. He demonstrated that a prism decomposes "white" light into a spectrum of colors. Newton obtained a triangular prism and began "to try therewith the celebrated Phaenomena of Colours." In his notes he states, "having darkened my chamber, and made a small hole in my window-shuts, to let in a convenient quantity of the Sun's light, I placed my Prisme at this entrance, that it might be thereby refracted to the opposite wall. It was at first a very pleasing divertisement, to view the vivid and intense colours produced thereby; but after a while applying

Newton, (Sir) Isaac,

Fig. 1 Newton's sketch of refracting sunlight with a prism. The experiment shows light passing through a hole and then collected by a lens and focused on the prism which then refracts white light into its spectral components. The experimental sketch also shows a second prism that is used to show a narrow band light is not further decomposed. A separate experiment was used to show the reversibility of the process

myself to consider them more circumspectly, I became surprised to see them in an oblong form, which, according to the received laws of Refraction, I expected should have been circular” [7]. The original sketch demonstrates the dark room environment where this experiment was conducted (Fig. 1). He was the first to use the word spectrum (Latin for “appearance” or “apparition”) in this sense. He also used additional prisms to recombine the split components and showed that a spectral colored light does not change its properties by separating out a colored beam and shining it on various objects regardless of whether it was reflected or scattered or transmitted. With respect to colors Newton said “For the rays, to speak properly, are not coloured. In them there is nothing else than a certain power and disposition to stir up a sensation of this or that Colour” [4]. During this period he also investigated the refraction of light and demonstrated that a multicolored spectrum produced by a prism could be recomposed into “white” light by a lens and a second prism [8]. In the same period Newton observed that the angle of refraction of different colors by a prism is different [9]. He noted that even when light rays in the form of a circular beam enter a prism, the spectrum of colors that exit in the position of minimum deviation is oblong. The length of the colored spectrum was in fact about five times as great as its breadth. He stated that it is the interaction of the object with light that creates the color of the object and not the object itself. This is known as Newton’s theory of color.

From this work, Newton concluded that the lens of any refracting telescope would be adversely affected by the dispersion of light into colors. This is also referred to as chromatic aberration. He constructed the first reflecting telescope in late 1668 using a mirror to avoid this problem, and this resulted in the first known functional reflecting telescope, which is today known as a Newtonian telescope [10]. Newton used a custom composition of highly reflective speculum metal to grind his own mirrors and then employed what is now known as “Newton’s rings” to judge the quality of the optics for his telescopes and demonstrated his device to the Royal Society in 1671 [11]. Their interest resulted in Newton publishing his notes, *Of Colours* [12], which was later expanded into his book *Opticks*. Newton was the first to demonstrate the use of a prism as a beam expander in his book and he describes, via diagrams, the use of multiple-prism arrays. Some 278 years after Newton’s discussion, multiple-prism beam expanders became central to the development of narrow-linewidth tunable lasers.

In 1704, Newton also discussed the corpuscular theory of light whereby light is considered to be made up of extremely small particles (which we now call photons). Newton argued that light is composed of particles or corpuscles, which were refracted by accelerating into a denser medium. To transmit forces between particles, Newton posited the existence of the ether. However, he replaced ether with occult forces based on Hermetic ideas of attraction and repulsion between

particles and Newton's considerable writings on alchemy. It has been said that "Newton was not the first of the age of reason: He was the last of the magicians." Indeed, Newton's interest in alchemy cannot be isolated from his contributions to science [11] since during his time there was no clear distinction between alchemy and science.

Later physicists favored a purely wavelike explanation of light to account for the interference patterns and the general phenomenon of diffraction. Later on, Young and Fresnel combined Newton's particle theory with the wave theory and indicated that color is the visible manifestation of light's wavelength.

The Color Circle

In his observation of white light dispersion into spectral components, Newton divided the spectrum into seven named colors: violet, indigo, blue, green, yellow, orange, and red. He placed the colors in a circular fashion and called it a color circle and used it to demonstrate the results of mixtures of spectral lights, including complementarity (those that when mixed cancel each other out and result in white, gray, or black). The size of each segment differed from the other according to his calculations of its wavelength, the seven musical tones or intervals of the eight sounds and of its corresponding width in the spectrum. The choice of seven colors was out of a belief, derived from the ancient Greek, that colors, objects in the solar system, the musical notes, and the days of the week were connected. This likely explains the selection of indigo as another hue between blue and violet. Some argue, however, that in Newton's prismatic colors, "indigo" would be placed as a color that is today called blue, whereas "blue" would correspond to cyan (Fig. 2).

Newton proposed a method to determine the "fullness or intenseness" of combined colors on the circle based on the distance of the center of the combined gravity of the circles for each of the rays of light from whiteness (the distance from O to Z in the figure shown for Color Y, which arises from the composition of all the colors in the given mixture). The color circle was, if lacking the non-spectral colors, an early representation of what became centuries later, in a modified form, the

Newton, (Sir) Isaac, Fig. 2 Colors and the associated musical notes in Newton's color wheel, shown in his book *Opticks* of 1704. The circle completes a full musical octave, from D to D [8]. Colors on opposite sides are complementary

chromaticity diagram. In his system, Newton had connected violet to red in the circle, and thus, a large gamut of purples was not shown. Newton described the complementary colors and their mixture and stated "If only two of the primary colours which in the circle are opposite to one another be mixed in an equal proportion, . . . , the colour compounded of these two shall not be perfectly white, but some faint anonymous colour." [8]. Newton's concept of complementary colors was demonstrated more thoroughly in the nineteenth century by color theorists. Helmholtz established the complementary stimulus pairs, and Ogden Rood (1831–1902) emphasized that to reveal applied colors in their natural brilliance, a knowledge of the complementary hues was required [13].

A version of Newton's color circle without the indigo blue was adopted by painters to describe complementary colors. Nonetheless, this circular diagram became the model for many color systems of the eighteenth and nineteenth centuries. The conceptual arrangement of colors in this form also allowed the painters' primaries (red, yellow, blue) to be arranged opposite their complementary colors (e.g., red opposite green), as a way of denoting that each complementary color would

enhance the other's effect through optical contrast.

In addition to his work on optics, Newton made seminal contributions to several other scientific disciplines. In his book the *Principia* or “*Mathematical Principles of Natural Philosophy*,” which was published in 1687, Newton formulated the laws of motion and universal gravitation and is considered to have laid the foundations for classical mechanics [14]. He also introduced the notion of a Newtonian fluid, studied the speed of sound, and developed an empirical law of cooling among other major contributions made to scientific discovery. Newton's image appeared on the Bank of England notes for about 10 years in the 1970s and 1980s [15]. He has also been commemorated on various stamps and coins [16] (Figs. 3 and 4).

Nickerson, Dorothy

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Dorothy Nickerson (August 5, 1900–April 25, 1985) was an American color scientist and

technologist who made important contributions in the fields of color quality control, technical use of colorimetry, relationship between color stimuli and color perceptions, standardization of light sources, color tolerance specification, and others. Nickerson was born and raised in Boston and attended Boston University in 1919 and Johns Hopkins University in 1923. Later, she continued her education at summer courses and university extensions at Harvard University, George Washington University, and the Graduate School of the US Department of Agriculture. Her special interest was the science of color then in significant development.

In 1921, Nickerson joined the Munsell Color Company as a laboratory assistant and secretary to A. E. O. Munsell who in 1918 had taken over the firm from his father. In 1922, the firm moved to New York and in 1923 to Baltimore. In 1927, she was offered a position at the US Department of Agriculture where she remained until her retirement in 1964. When she joined, color science and technology were without international standards and at the beginning of industrial use. Nickerson was instrumental in developing the technology and its use in agricultural and industrial settings.

Nickerson became the first individual member of the Inter-Society Color Council, founded in 1931. She was a lifelong member, received the organization's Godlove Award, and had an award named after herself. She was a member of the US National Committee of the CIE and the International Association on Color where she received the first D. B. Judd AIC Award in 1975. Nickerson was a trustee of the Munsell Color Foundation since 1942, was its president from 1973 to 1975, and assisted in the transfer of the foundation to the Rochester Institute of Technology in 1983 where it helped fund the then new Munsell Color Science Laboratory. Nickerson was the author and coauthor of some 150 articles and other publications [1].

Major Accomplishments/Contributions

Color quality control of agricultural products: In the late 1920s, Nickerson worked on usage of disk

color mixture to define the color quality of cotton and other agricultural products (see portrait image, ca. 1930, US Government) and the conversion of disk mixture data into the CIE colorimetric system [2].

Standardization of light sources for color assessment and color rendering: In the late 1930s, a major occupation of her was the development of defined light sources for visual assessment of color quality. Later, she was also active in the development and promotion of standard methods for the definition of color rendering of lights [3].

Munsell color system and its colorimetric definition: In 1940, a technical committee of the Optical Society of America (OSA) began a study of the Munsell color system, improvements and extensions of the system, and its definition in the CIE colorimetric system. Nickerson was an important participant in this effort. The final report of the committee was authored by S. M. Newhall, D. Nickerson, and D. B. Judd, and its results are known as the Munsell renotations, the specification of the aim colors of the current system. Nickerson prepared plots of the Munsell color stimuli in the CIE chromaticity diagram that remain in publication today [4, 5]. She also wrote an extended history of the Munsell system [6].

Color tolerance specification: In 1936, Nickerson published the first color difference formula for industrial use, based on the addition of increments of Munsell hue, chroma, and lightness scale values. In 1943, together with Newhall, she published realistic representations of a three-dimensional perceptually approximately uniform optimal object color solid. In 1944, together with her assistant K. F. Stultz, she published a colorimetric color difference formula, known as the Adams–Nickerson–Stultz formula, that in modified form eventually became the CIE $L^*a^*b^*$ color space and difference formula [7, 8].

Color charts: In the mid-1940s, Nickerson was active in methods for assessing the color of soils, an effort that found its expression in the Munsell Soil Color Chart, still in use today. In 1957, Munsell issued the Nickerson Color Fan, a color

fan for horticultural purposes [9]. Working with D.B. Judd, the chair of the OSA committee that developed the OSA Uniform Color Space, Nickerson, as a member of the committee, was also a contributor to that effort for over 25 years and wrote a detailed history of the development of the system [10].

Non-photorealistic Rendering

Jorge Lopez-Moreno
GMRV Group, Universidad Rey Juan Carlos,
Madrid, Spain

Synonyms

Artistic rendering; Computer depiction; Expressive rendering

Definition

In computer graphics, non-photorealistic rendering (NPR) describes all the depiction techniques which do not aim to convey photographic realism. The reason why this term is defined by “what it is not” is that through the last decades, the computer graphics community has focused most of its efforts in creating images indistinguishable from reality (like a photograph or photorealistic), thus assimilating the subfield “photorealistic rendering” to the more general term “computer graphics.”

Some of the most well-known NPR techniques are 3D rendering with *cel shading* to simulate cartoon style, simulation of traditional art media (ink, pencil, watercolor, etc.) and artistic styles (abstract painting, impressionism, etc.), and technical depiction of objects in order to enhance clarity over realism: architecture blueprints, engineering cutaway, and explode views or anatomical dissections.

Origin of the Term

The term was coined by Salesin and Winkenbach in 1994 [1] and although its widespread use by researchers around the world, it is not free from controversy. Since the first International Symposium on Non-photorealistic Animation and Rendering (the most well-known research conference on this subject) in the year 2000 [2], there is an ongoing discussion over the looseness of this term, and several alternatives have been proposed such as “computer depiction” [3]. One reason is that *non-photorealistic* only describes a style of generating images, while the range of topics in NPR research encompasses both rendering aspects (multiple styles of picture generation) and interaction issues (e.g., artistic tools such as a simulated brush).

Related Fields: Art and Perception

The motivation for NPR is that realism by itself is not always desirable in order to communicate

something about the scene to be depicted. For instance, painters like Van Gogh or Munch used extremely saturated and unrealistic colors and paint strokes in order to convey not only the depicted object but also a certain mood or feeling. Likewise but not for artistic reasons, stylized illustration is preferred over real images in medicine to teach anatomy, as they help in differentiating the parts of the human body which are otherwise difficult to identify in their natural state (see Fig. 1).

Given this range of applications, the NPR field has naturally embraced interdisciplinary collaboration both with the artistic community and human perception researchers: in the last decade as applications like augmented reality move away from photorealism in a wish for conveying additional or specific information (e.g., overlaid pathology data during a surgery intervention), a strong need arises for checking that the depiction that they do provide faithfully communicates the desired information.

This interaction between art, perception, and NPR is widespread in the literature. Researchers have studied how humans paint or draw in order to derive models which predict the success of NPR algorithms [4]. For instance, by combining several depictions of the same object made by different persons, it is known that most of the strokes

Non-photorealistic Rendering, Fig. 1 Illustration of a heart inferior wall dysfunction (short and long axis views). (By Patrick J. Lynch (medical illustrator) and C. Carl Jaffe (MD, cardiologist))

can be predicted thanks to three-dimensional features such as contours or curvature and thus are automated by line drawing methods like *suggestive contours* [5]. However, it is also evident in these studies that even the most recent and sophisticated methods fail to predict all the elements used by artists to draw an object.

Artistic styles have also been analyzed and, when possible, simulated from the physical media (e.g., simulation of fluids for paint) to the gamut of colors or the strokes and the shapes [6]. Rendering in a specific style usually implies a combination of multiple NPR techniques: Fig. 2 shows some of the image processing methods used for rendering stylized depictions. Although most of these techniques still require a significant amount of user input (in choosing and combining multiple parameters), in recent years, some approaches for automatic abstraction or color and histogram matching have been proposed [7, 8].

In recent years, algorithms based on deep learning have achieved very good results of painterly style transfer, that is, transforming real photographs or synthetic renderings into exemplars of specific artistic styles. This is the case of the work

by Luan et al. [9] where they achieve multiscale harmonization of photographs inserted into paintings by means of a VGG network and two consecutive passes for coarse harmonization and subsequent localized detail texture similarity enforcement.

Classification

The works in the field are usually classified by their input system (2D, 3D) and type of user input (assisted or automatic):

- **From 3D to 2D:** Given a 3D geometric description of the objects, their material properties and light sources, a 2D image is generated according to a non-photorealistic style. For instance, in the cel shading technique, hand-drawn cartoon style is mimicked by adding a black contour line (occluding contour) based in the culling of front faces in the geometric model and illuminating the object with a flat shading obtained by limiting the range of colors to 2 or 3 t. The continuous value yielded by traditional shading formulae

N

Non-photorealistic Rendering, Fig. 2 Some examples of 2D NPR stylization. *Top row:* input images. *Bottom row:* resulting depictions, from *left to right* – oil strokes

simulation based on flow integration (LIC), edge detection with color posterization, and abstraction based in hue shift and pixel splattering

Non-photorealistic

Rendering, Fig. 3 Toon shading render generated with available commercial software. The 3D model in the *left* was created with a subsurface scattering shading technique. The NPR version in the *right* includes shadows, contour lines, and three shades of gray

(based on the cross product of the vertex normals and the direction of the light source) is thresholded to a limited set of values to produce this effect (Fig. 3). Nowadays, most of these rendering effects are generated as a postprocessing step in image space. Surface normals, depth, and reflectance values are computed per pixel and stored as images in different layers (a technique known as deferred shading). In this context, image processing is used to the same effect. For instance, contour lines can be generated by detecting discontinuities in the normal image with an edge filter such as Canny's detector [10].

- **From 2D to 2D:** This is usually based on image processing techniques and no user intervention. Most of the commercially available photo cameras provide at least a few of these transformations. Given a photograph as input, a purely 2D cel shading effect is obtainable by a combination of histogram thresholding (*posterize*) for color and a contour detector (Canny) for the contour lines. The simulation of brush and pencil strokes by using *line integral convolution* (LIC) [11] is another well-known example, which integrates random sampling from the luminance vector field of the original image in order to generate lines emulating the most likely strokes done by artists (see bottom left image in Fig. 2). Saliency

and feature detection are also considered to emphasize those strokes which have greater visual significance.

- **From 2.5D to 2D:** That is, 2D plus additional data such as incomplete 3D information (depth range or *Z-buffer*) and/or user annotations – semantic tags (*this part of the image is a cloud*), strokes (which encode information in its shape), marks (*this part of the object is on top to the other*), etc. Some recent techniques [12] include perception assumptions (such as *global convexity* and *saliency*) in order to infer depth from 2D images. This depth can further be edited (sculpted) with brush strokes or directly used in combination with traditional 3D-to-2D algorithms to render NPR images like those in Fig. 4.
- A fourth possibility is **from 2D to 3D**, that is, from a set of user strokes or images (or a combination of both) of a given scene, a 3D model is derived which allows for novel views. This conforms a field by itself called *image-based modeling and rendering* (IBMR), which lies between the areas of computer graphics and computer vision.

Examples

Since the early adoption of cel shading in the title *Jet Set Radio* (year 2002), hundreds of examples

Non-photorealistic Rendering, Fig. 4 Example of perception-based NPR rendering from Ref. [12]. *Top left*: original photo. *Top right*: multitone depiction obtained

from hallucinated depth and virtual light sources. *Bottom left*: additional comic book style result with two layers of dynamic lines added. *Bottom right*: NPR color relighting

N

of NPR techniques have emerged in video games. Likewise, NPR is ubiquitous in animation and films. The *South Park* series is an unexpected example of 2D cartoon style derived from 3D models. A case of 2D real-life footage to 2D hand-drawn animation style is shown in the film *A Scanner Darkly*, where key frames were roto-scoped and vectorized, automatically interpolating the frames in between. However, although some automation processes were introduced, this production required a significant amount of user input.

More recently, the aesthetic currents reminiscent of 8-bit and 16-bit games and systems have contributed to the popularity of *pixel art*, where images and animations (sprites) are edited on the pixel level, with deliberate control over the placement of individual pixels, often with the intent of maximizing the expressivity of the rendering with a minimalistic set of lines, colors, and gradients

Non-photorealistic Rendering, Fig. 5 Example of Pixel Art, artwork derived from videogame *Sancho Island*

(see Fig. 5). *Pixel art* is usually rendered in 2D, but upcoming games (year 2021) such as *The last Night* or *Replaced* have translated this technique to hybrid 3D environments, combining it with physically based illumination and complex volumetric shading effects.

[Circadian rhythms](#); [Circadian system](#)

Definition

Biological, nonvisual effects of lighting constitute a growing field within lighting research and education. In addition to visual effects, light is known to affect other biological rhythms, most notably the circadian system, which generates and regulates a number of rhythms that run with a period close to 24 h. Light/dark patterns incident on the retina are the major synchronizer of circadian rhythms to the 24-h solar day. Lighting characteristics (quantity, spectrum, timing, duration, and distribution) affecting the visual and circadian systems differ. Symptoms of circadian sleep disorders, such as seasonal affective disorder, jet lag, and delayed sleep phase disorder, can be mitigated by timed light exposure.

Introduction

The neurophysiology and neuroanatomy of the human visual system are largely understood: vision is the result of complex interactions between light sources, objects and surfaces, the eye, and the brain. Lighting engineers and practitioners have developed technologies, standards,

measurement devices, and applications based on this knowledge, and one of the primary goals of lighting design is to increase performance and productivity by improving vision and perception. Recent scientific discoveries, however, have added another dimension to lighting: namely, that *light is not just for vision anymore*. Specifically, scientists have discovered that daily light/dark patterns reaching the retina (back of the eye) play an important role in human health and well-being because they regulate our bodies' circadian rhythms. Circadian rhythms are every rhythm in our body that repeats approximately every 24 h. The circadian system is profoundly important for many human behaviors, as well as human well-being.

This entry provides basic knowledge about the nonvisual effects of light entering the eye, focusing exclusively on the effects of light on human circadian and diurnal rhythms. Also discussed here are the lighting characteristics that affect these rhythms, as well as applications in which light/dark cycles have been experimentally shown to affect them.

Overview of the Circadian System

Earth rotates around its axis, and, as a result, all creatures exposed to daylight on Earth experience a 24-h cycle of light and dark. Living organisms have adapted to the planet's daily rotation by developing biological rhythms that repeat at approximately 24-h intervals [1]. These rhythms are called circadian rhythms, from the Latin *circa* (about) and *dies* (day).

Biological Clock

Circadian rhythms are generated internally by the body, yet they are constantly aligned with the environment by factors that are external to the body, mainly light/dark cycles. In mammals, circadian rhythms are regulated by an internal biological clock located in the suprachiasmatic nuclei (SCN) of the hypothalamus of the brain. The biological clock in humans has a natural period that is slightly greater than 24 h, and

environmental cues, such as light/dark cycles, social activities, and meal times, can reset and synchronize the clock daily, ensuring that our behavioral and physiological rhythms are synchronized with the external environment.

Output Rhythms

Output rhythms are behavioral and physiological rhythms regulated by the biological clock, such as the sleep/wake cycle, alertness, core body temperature, locomotor activity, feeding and drinking behavior, and hormone production. Of special interest here are the sleep/wake cycle, alertness, core body temperature, and hormone production, especially melatonin production.

Sleep/Wake Cycle and Alertness

The sleep/wake cycle is one of the most prominent circadian rhythms. We are under the influence of two opposing systems: the sleep drive (homeostatic) and the alerting force (circadian). The sleep drive and the alerting force are distinct forces, independent from each other, though complementary, ensuring that we are asleep at night and awake during the day. The sleep drive, for example, is low when we get up, increasing steadily throughout the waking day, before diminishing rapidly within the first hours of sleep. The alerting force is regulated by the biological clock and follows a circadian rhythm, reaching a peak during the early evening and a trough during the second half of the night. The interaction between the sleep drive and the alerting force determines when we fall asleep and how well we sleep at night. Alertness is strongly correlated with the sleep/wake cycle.

Core Body Temperature

Core body temperature also follows a circadian pattern. It is high during the day, reaching a peak in the early evening, and low at night, reaching its low point about 2 h before one naturally wakes up. Core body temperature is typically in phase with alertness and has a negative correlation with the hormone melatonin. The alerting force is at its minimum during the second half of the night, close to the core body temperature minima.

Hormone Production

Although there is evidence that the biological clock influences a variety of hormones, this discussion will be limited to melatonin production by the pineal gland. The pineal gland is located near the center of the brain, is about the size of a pea, and has a shape resembling that of a pinecone. It is believed that the primary function of the pineal is to convey light/dark information to the body via secretions of the hormone melatonin [2]. Melatonin is easily absorbed into the bloodstream, which makes it an ideal chemical messenger of time of day information for the entire body. Melatonin also participates in the transmission of information concerning day length or photoperiod for the organization of seasonal responses in animals (e.g., breeding).

Melatonin is produced during the subjective night (i.e., inactive period in diurnal species and active period in nocturnal species) and under conditions of darkness. As a result, melatonin levels are low during the day and high at night (in the dark). Although not yet well established, many researchers believe that melatonin can induce sleep in diurnal mammals, including humans, by acting on the SCN and reducing the alerting force, or the “wake-promoting” signal sent by the biological clock during the daytime. In addition, melatonin has an inverse relationship with core body temperature, which is closely linked to waking and sleep times. Peak melatonin levels typically occur slightly before core body temperature bottoms out. When external cues are absent, melatonin starts being endogenously produced by the body at around 9–10 p.m. (or about 2 h prior to sleeping) and stops being produced at around 7–9 a.m. Maximum melatonin levels occur between 2 and 4 a.m [2].

Regulation of Circadian Rhythms by Light

The 24-h light/dark cycle is the biological clock’s main synchronizer to the solar day. Light can phase advance or phase delay human circadian rhythms, depending upon when it is applied [3]. For example, light that is applied before the

minimum core body temperature, which is reached approximately 1.5–2.5 h before we naturally awaken, will delay the clock (e.g., one will wake up later the following day), and light applied after minimum core body temperature is reached will advance the clock (e.g., one will wake up earlier the following day). Although light is the main synchronizer of the biological clock to the solar day, it is not the only one. Exercise, social activities, timing of the sleep/wake cycle, and scheduled meals have also been shown to shift and synchronize the clock, although their impact on circadian rhythms seems to be weaker than the impact of light/dark cycles.

Lighting Characteristics Affecting Circadian Rhythms

The neural machinery in the mammalian retina provides light information to both the visual and circadian systems, but the two systems process optical radiation (light) differently [3]. Rods, cones, and the intrinsically photosensitive retinal ganglion cells (ipRGCs) [4] participate in circadian phototransduction (how the retina converts light signals into electrical signals for the biological clock). The quantity of polychromatic “white” light necessary to activate the circadian system is at least two orders of magnitude greater than the amount that activates the visual system. The circadian system is maximally sensitive to short-wavelength (“blue”) light, with a peak spectral sensitivity at around 460 nm (Fig. 1), while the visual system (i.e., acuity) is most sensitive to the middle-wavelength portion of the visible spectrum, with a peak at around 555 nm. Operation of the visual system does not depend significantly on the timing of light exposure and, thus, responds well to a light stimulus at any time of the day or night. On the other hand, the circadian system is dependent on the timing of light exposure, as discussed above. In addition, while the visual system responds to a light stimulus very quickly (in milliseconds), the duration of light exposure needed to affect the circadian system can take minutes. For the visual system, spatial light distribution is critical for good visibility. It is not yet well established how light incident on different portions of the retina affects the circadian system.

Nonvisual Lighting Effects and Their Impact on Health and Well-Being, Fig. 1 Photo of light goggles engineered by the Lighting Research Center. For the same photopic lux at the eye, “blue,” short-wavelength light has the greatest impact on the circadian system

It is also important to note that the short-term history of light exposure affects the sensitivity of the circadian system to light; the higher the exposure to light during the day, the lower the sensitivity of the circadian system to light, as measured by nocturnal melatonin suppression and phase shifting.

Specifying Light for the Circadian System

In 2005, Rea et al. proposed a mathematical model of human circadian phototransduction based on the neuroanatomy and neurophysiology of the human retina and using published action spectrum data for acute melatonin suppression [5, 6]. Using this model, spectral irradiance at the cornea is first converted into circadian light (CL_A), which is comparable to photopic illuminance but weighted by the spectral sensitivity of the human circadian system (Fig. 2a) as measured by acute melatonin suppression after a 1-h exposure. Then the circadian stimulus (CS) is determined, which reflects

the effectiveness of the spectrally weighted irradiance at the cornea from threshold ($CS \approx 0.1$) to saturation ($CS \approx 0.7$) (see Fig. 2b). While CS was developed using data from studies that measured acute melatonin suppression, Zeitzer et al. [7] showed that acute melatonin suppression and phase shifting of melatonin rhythms followed similar threshold and saturation response characteristics. The model has been successfully used to predict the effectiveness of various light sources for activating the circadian system in laboratory [8–13] and field studies [14–18].

Measuring Light for the Circadian System

Given that lighting characteristics affecting the visual system are different from those affecting the circadian system and that commercial light meters are calibrated to measure light for the visual system, new measurement devices that properly characterize light for the circadian system are needed. Two similar devices, the Daysimeter-S and the Daysimeter-D (also known as Dimesimeter), have been developed [19]. They are personal circadian light meters that measure light that is effective for visual and circadian responses. The Daysimeter-S has the photosensor package positioned near the plane of one cornea, and the Daysimeter-D can be worn as a pin, as a pendant, or on the wrist (Fig. 3). These photosensors are calibrated to measure “circadian” light. They also provide accurate measurements of light for vision (photopic lux). The photosensor package closely matches the eye’s acceptance of angles of light. Since circadian rhythms follow a 24-h pattern, it is necessary to measure light (and dark) over extended time periods to ascertain the stability and period of circadian rhythms. To this end, the Daysimeters can be deployed in the field to gather light data for up to 30 days with a 30-s sampling interval.

Applications

In the following section, practical situations in which the effects of light on the circadian system could be beneficial to human health and well-being will be discussed. It is important to note

Nonvisual Lighting Effects and Their Impact on Health and Well-Being, Fig. 2 The photopic illuminance ($V(\lambda)$) circadian light (vision) spectral efficiency

functions (a) and the absolute sensitivity of the human circadian system to light (b)

Nonvisual Lighting Effects and Their Impact on Health and Well-Being, Fig. 3 (a, b) Photo of the Daysimeter-D worn on the wrist and as a pin

that light is not currently known to cure any diseases. Further, individual differences need to be considered when designing lighting for the circadian system, so the lighting recommendations discussed below should be used as a framework only, and adjustments must be considered. It is also important to emphasize that few of the studies using light as a non-pharmacological treatment for various diseases and disorders reported the spectral power distribution of the light source, which makes it difficult to quantify the impact of light on the retina for circadian effectiveness. Consequently, generalizations from these studies are often more qualitative (e.g., bright vs. dim) than quantitative.

Tentative application tips will be made, and the quantity, spectrum, duration, and timing of the light presented at the eye will be discussed. In order to simplify and standardize the tips offered here, **bright white light** will be defined as 1-h exposure to a CS of 0.3 (at least 500 lx measured at eye level from a white light source), unless otherwise stated in the text. This light level is about five times the amount of light one typically finds in an office environment without a window. “Blue” light is defined here as 1-h exposure to 40 lx at the cornea from a narrowband light source peaking at 470 nm. If duration of exposure is increased, light levels may be decreased, but it is recommended that it is never below a CS of 0.2 (roughly 300 lx at the cornea for the white light)

and 20 lx at the cornea for the blue light. The lighting recommendations offered here are based on current knowledge from research findings, but results of future research will refine these values.

Seasonal Affective Disorder

Seasonal affective disorder (SAD) is a subtype of depression, with episodes occurring during winter months and remitting during summer months. Symptoms of SAD include depression, hypersomnia, and weight gain due to increased carbohydrate cravings, social withdrawal, and even suicidal thoughts. It is believed that because daylight availability decreases in the winter at high latitudes, the number of people experiencing SAD increases as the latitude increases. “The winter blues” is an even more common subtype of SAD. The mechanisms of SAD are still unknown, and there are several competing hypotheses as to what causes SAD and how light can be used as a treatment. One of these is that late daybreak during winter months delays the circadian rhythms of those more susceptible to SAD; in this case, morning light is believed to be effective in treating symptoms of SAD. Another hypothesis is that the overall melatonin production of those suffering from SAD is greater during winter months than during summer months, which extends the amount of time during the 24-h day that their bodies think it is nighttime. In this case, light in the early morning or evening is recommended.

If a person is formally diagnosed with SAD by a general practitioner, insurance companies may pay for the cost of light treatment devices. A recent study [20] showed that approximately 500 lx of blue light ($\lambda_{\max} = 470$ nm) directed at the eye was able to significantly improve SAD symptoms compared to red light used for placebo control. It has been suggested, however, that the positive impact of light on SAD symptoms is simply a result of placebo effects.

Practical Tips

- Encourage SAD patients to go for a half-hour walk outdoors in the morning (right after daybreak).
- Expose individuals to bright white light (or “blue” light) in the morning or evening.

Jet Lag

Jet lag is a temporary desynchronization between the biological clock time and the environmental time (light/dark). The symptoms include insomnia and/or hypersomnia, fatigue, poor performance, and gastrointestinal problems. Eastward travel generally results in difficulty falling asleep, and westward travel results in difficulty maintaining sleep. Adaptation to a new time zone is usually slower after eastward travel than after westward travel. This is because [1] those traveling east need to advance their biological clock to readjust to local time at their destination; the time that daylight is available upon arrival at the final destination will promote phase delay of the biological clock, and [2] it is easier for the timing of the biological clock to be delayed than advanced. One study [21] showed that a combination of advancing sleep schedules for 1 h per day plus morning light treatment (one half hour of 5,000 lx + half hour of less than 60 lx at the cornea) for 3.5 h advanced the phase of the biological clock by 1.5–1.9 h in 3 days. Although the principles for applying light treatment for reducing jet lag symptoms are known, the implementation of the light treatment may be a challenge. Airlines are starting to use colored light inside airplanes to improve mood, but it is probably very difficult to shift the biological clock to promote complete adjustment to a new time zone while one is inside the plane. Because the circadian clock is slow to shift, users need to start treatment a few days before they are scheduled to travel. However, because travelers have busy schedules, the likelihood of compliance is low. A personal light treatment device could be developed to increase the likelihood of compliance (Fig. 4).

Practical Tips

- Eastward travel: Upon arrival at your destination, avoid bright white light (including daylight) during the morning, until about noon local time, and seek exposure to bright white (or “blue”) light in the afternoon. Upon arrival, wear glasses that filter out radiation below 520 nm (“orange” glasses; Fig. 5) to avoid circadian-effective light because the circadian

Nonvisual Lighting Effects and Their Impact on Health and Well-Being, Fig. 5

Orange goggles are able to block short-wavelength light that maximally activates the circadian system. These goggles should be worn at times when one wants to reduce circadian effective light exposures

system is maximally sensitive to short-wavelength (“blue”) light.

- Westward travel: Upon arrival at your destination, seek exposure to bright white light (or “blue” light) during the daylight hours and avoid bright white light in the evening.

Delayed Sleep Phase Disorder

Delayed sleep phase disorder (DSPD) is a disorder of sleep timing; people suffering from DSPD typically go to bed late and wake up late (3–6 h later than typical sleeping hours). This pattern interferes with people’s normal functioning because they have difficulty waking up in the

morning for work, school, and social obligations, and since they go to bed late, they do not sleep for as many hours as those going to bed at more normal hours. DSPD in adolescents is common and probably associated with hormonal changes that occur at puberty. The exact causes of DSPD are not actually known, but light exposure after minimum core body temperature and dim light during the evening have been shown to advance the phase of the biological clock of persons with DSPD [22]. Using this information, field studies [23] were conducted to investigate the impact of light exposures on dim light melatonin onset (DLMO), a primary marker for the timing of the

biological clock, and on sleep duration for two populations of eighth graders. It was hypothesized for one study conducted in North Carolina that the lack of morning short-wavelength light (which was removed by wearing orange goggles; Fig. 5) would delay the timing of the students' biological clocks. For the other study conducted in New York, it was hypothesized that exposure to more evening light in spring relative to winter would also delay the biological clocks of adolescents. In both studies, as expected, the students exhibited delayed DLMO as a result of removing short-wavelength morning light and as a result of seasonal changes in evening daylight. Also as expected, both sets of adolescents exhibited shorter sleep times; because of the delay in the timing of the biological clock, they fell asleep later but still had to get up at a fixed time in the morning. These two field studies clearly demonstrate that by controlling circadian light exposures, it is possible to practically and effectively control circadian time and thereby affect meaningful outcomes like sleep duration.

Practical Tips

- Expose individuals to bright white (or "blue") light in the morning, after the minimum core body temperature. Note that minimum core body temperature of people with DSPD may occur as late as 9 a.m.; therefore, an understanding of the characteristics of the biological clock of those using the light treatment is needed before recommending the timing of the light exposure. Just as a tip, minimum core body temperature generally occurs 1.5–2.5 h prior to waking without an alarm clock.
- Wear glasses that filter out radiation below 520 nm ("orange" goggles; Fig. 5) in the evening and in the morning, before minimum core body temperature is reached. Because the circadian system is maximally sensitive to short-wavelength light, elimination of optical radiation below 520 nm at these specific times will reduce the chances of phase shifting the biological clock to a later time, aggravating symptoms of DSPS even further.
- Avoid the use of very bright self-luminous electronic devices (e.g., computer screens, tablets, and cell phones) during the evening hours. At a minimum, dim them down or filter their screens with "orange" filters.

Sleep in Older Adults

Sleep disturbances in older adults. Seniors living in controlled environments (assisted living and nursing homes) are perhaps the best example of a population at risk for circadian sleep disorders; due to age-dependent reduced retinal light exposures and to fixed lighting conditions in their living environments, seniors are less likely to experience the necessary, robust 24-h, light/dark pattern needed for circadian entrainment. Prescribed 24-h light/dark patterns have been shown to influence circadian rhythms and thereby alleviate some sleep and agitation issues common among seniors, including those with Alzheimer's disease (AD). A 24-h lighting scheme has been proposed that delivers high circadian stimulation during the daytime hours, low circadian stimulation in the evening hours, and night lights that provide perceptual cues to decrease the risk of falls at night [24], such as those shown in Fig. 6. Studies showed that exposure to bright white light (ranging from 2,500 lx to as high as 8,000 lx at the cornea) for at least 1 h in the morning for a period of at least 2 weeks was found to improve or consolidate nighttime sleep of AD patients. Greater sleep efficiency at night decreased the need to sleep during daytime hours and, in some cases, reduced agitated behavior such as pacing, aggressiveness, and speaking loudly. Research demonstrated that exposing 22 AD patients to continuous, bright, and indirect white light (average of 1,136 lx at the eye) over 4 weeks consolidated their rest/activity rhythms [25]. In a long-term study, it has been demonstrated that light attenuated cognitive deterioration by 5% on the mini-mental state examination. Light also ameliorated depressive symptoms by 19% on the Cornell Scale for Depression in Dementia and attenuated the increase in functional limitations over time by 53% on the nurse-informant activities of daily living scale or a relative 53% difference [26].

Nonvisual Lighting Effects and Their Impact on Health and Well-Being, Fig. 6 Novel nightlighting system using horizontal/vertical cues that can improve postural control and stability

Practical Tips

- For older adults who want to fall asleep later in the evening, expose them to bright white (or “blue”) light in the late afternoon/early evening (before 7 p.m.), before minimum core body temperature. It is recommended that the duration of the exposure be increased to 2 h or the quantity of light be increased by a factor of two because of the optical changes to the aging eye.
- Wear glasses that filter out radiation below 520 nm (“orange” goggles) in the very early morning hours (before 7–8 a.m.).
- For AD patients who do not have a consistent sleep/wake schedule, expose them to bright white (or “blue”) light at any time during the day and reduce evening light exposures. Be consistent with the timing of the light exposure, however. Because the circadian phase of AD patients is not known and because they tend to remain in continuous dim light all day, it is expected that a robust light/dark pattern will positively impact their sleep.
- Install safe nightlighting systems that provide low-level illumination and perceptual (horizontal/vertical) cues to aid in controlling postural control and stability (Fig. 6).

Entrainment for the General Population

As shown in the examples above, lighting can help reduce or mitigate symptoms associated with various circadian sleep disorders. Lighting can also aid in maintaining entrainment in the healthy, general population. Because humans have a biological clock that runs with a period slightly greater than 24 h, we need daily morning light exposure to maintain entrainment to the solar day. In winter months, some of us can go to and come back from work or school in darkness; therefore lighting in our work environments should provide enough circadian stimulation during at least the morning hours. Although the link between circadian entrainment and productivity is yet to be established in larger, clinical studies, one study [27] to date showed that compared with a 4,000 K light source, blue-enriched white light (17,000 K) improved subjective measures of alertness, positive mood, performance, evening fatigue, irritability, concentration, and eye discomfort. Daytime sleepiness was reduced, and the quality of subjective nocturnal sleep was improved under blue-enriched white light. More recently, two field studies conducted in nine US federal government office buildings showed that both morning [17] and all-day [28] exposures to a

CS of at least 0.3 improved objective measures of circadian entrainment and sleep quality (actigraphy) and subjective measures of sleep disturbances, daytime sleepiness, depression, vitality, and energy (questionnaires) in office workers. Although future studies should confirm and extend these results, it is suggested that a dynamic lighting system that delivers bright white light (or “blue” light) to office workers during the morning hours can help maintain entrainment and possibly improve well-being, alertness, and performance, especially in winter months, when duration of daylight availability is short [29].

The Future

This overview of the impact of light on the circadian system and its effects on our health and well-being underscores the importance of developing a new framework for lighting practices that includes not only those lighting characteristics that affect the visual system but also those that affect the circadian system. Because there are great differences between the two systems’ responses to the quantity of light, its spectral composition, spatial distribution, timing, and duration, generalizations about “quality lighting” will have to be assessed by two very different sets of criteria in the future. Although the information and recommendations presented here will certainly be refined as more research is undertaken, little progress will be made in delivering “healthy lighting” to society until researchers and practitioners begin to consider, measure, calculate, and control the fundamental characteristics of light for the circadian system. Hopefully, this entry will serve as an important step toward that goal.

Finally, it is important to remember that we have no practical way to intuitively know when and what type of light we need for circadian entrainment. Like other medical monitors where we have no conscious access to what we need for good health (e.g., glucose monitors for diabetes), we need technologies to measure and track the state of our circadian system. A wireless technology connecting the Daysimeter to a smartphone is currently under development. A smartphone

(or similar technology) will be able to interpret the light/dark patterns to which a person is exposed and then be able to recommend, based on models of human circadian entrainment [30], both current and future light exposure patterns for the user to maintain circadian entrainment. One day, the smartphone might be able to interface with the building lighting system itself so that children in a school, nurses in a hospital, or people at home would be exposed to the proper lighting conditions for maintaining well-being and for increasing productivity.

Optic Chiasm, Chiasmal Syndrome

Jonathan Aboshiha
The UCL Institute of Ophthalmology and
Moorfields Eye Hospital, London, UK

Synonyms

[Chiasma opticum](#)

Definition

The **optic chiasm** (from the Greek for “cross-piece”) is the anatomical location where the two optic nerves, having left the eyes, join together before then separating once more as the two distinct optic tracts, thus forming an anatomical “X.” **Chiasmal syndrome** is the name given to the group of symptoms and signs that occur together as a result of lesions affecting the optic chiasm.

Overview

Optic Chiasm

This optic chiasm measures 15 mm in width and 3.5 mm in height [1] and has several important structures located adjacent to it; below the optic

chiasm, in a bony excavation called the sella turcica, lies the pituitary gland, and either side of it are found the venous cavernous sinuses, which transmit the internal carotid artery and several important cranial nerves. The frontal lobe of the brain sits above the chiasm, and the floor of the third ventricle lies behind. The optic chiasm is significant because it is here that the visual signals coming from each retina decussate, and so from this point onward, there is representation from both eyes on both sides (i.e., left and right sides) of the visual pathway. The nasal optic nerve fibers, carrying signals from the nasal retinae (and hence temporal hemi-fields of vision), cross or decussate to the other side (contralateral) at the optic chiasm, while the temporal fibers, which carry signals from the temporal retinae (and hence nasal hemi-fields of vision), continue on the same side (ipsilateral). In anatomically normal individuals, approximately 50% of the axons (i.e., those from the nasal retina) decussate across the midline to join the uncrossed fibers traveling toward the brain from the temporal retina. These fibers exit the chiasm to form the left and right optic tracts, which carry signals from the right and left hemi-fields of vision, respectively. In certain conditions, the proportion of crossing fibers at the chiasm is significantly different from the 50% value observed in normals; in humans with albinism, a greater number of fibers from temporal retina decussate and project contralaterally [2].

Chiasmal Syndrome

Pathology in any of the key anatomical structures that lie adjacent to the optic chiasm (see above) has characteristic effects on the optic chiasm, giving rise to a unique constellation of visual signs and symptoms, collectively known as the chiasmal syndrome. Depending on the particular pathology involving these adjacent structures, and the consequent relative location of damage to the chiasm, the exact features seen in any chiasmal syndrome can help anatomically locate the site of the lesion.

A visual field defect may be the earliest sign of a lesion at the optic chiasm [3], and the classical visual field defect seen in chiasmal syndrome is the loss of the temporal hemi-fields of vision in both eyes (so-called bitemporal hemianopia). This is caused by a lesion in the body of the chiasm which damages

the crossing nasal retinal fibers. Any lesion of the chiasm (such as a tumor, vascular lesion, traumatic lesion) may cause this, and there are subtle variations in the extent of the bitemporal hemianopia that can help give clues as to the causative lesion. The exact field defect will vary according to the type of lesion and the precise individual anatomical relationship of the chiasm to the structures that surround it. The most common cause of such a field defect is a tumor of the pituitary gland [3]. The visual acuity may also be reduced, as may the color vision on testing with pseudoisochromatic plates, with a tendency to have more severe red-green deficits and milder blue-yellow losses [4].

Lesions of the anterior chiasm can cause a so-called junctional scotoma, presenting with a central field loss in one eye and a superotemporal field loss in the other – this is classically said to be due to a small bundle of inferonasal nerve fibers that briefly loop forward in the contralateral optic nerve, called Wilbrand's knee. More recently, the existence of Wilbrand's knee has been questioned as an artifactual error, relating to the fact that the cadaveric specimens on which the observation of this anatomical feature had been based had always suffered the loss of one eye before death [5], and investigations have found no clinical perimetric evidence to support the existence of this anatomical feature in human beings [6].

Lesions of the posterior chiasm may cause an uneven field loss in both eyes of the visual field on the same side, due to damage to the optic tracts (i.e., an incongruous homonymous hemianopia).

Compression of the optic chiasm may also cause atrophy of the nasal nerve fibers, with the superior and inferior nerve fibers being relatively spared – so-called “bow-tie” optic atrophy – as well as an unusual type of nystagmus (an involuntary movement of the eyes) called “seesaw” nystagmus [7]. Loss of the temporal visual fields can lead to postfixation blindness and the inability to keep the eyes both facing in the same direction, a phenomenon known as hemi-field slide [8].

The optic chiasm also lies close to a venous space (the cavernous sinus) where the nerves that control eye movement pass – lesions in this area can damage these nerves and cause further problems with the eyes moving together, resulting in diplopia (double vision).

Anyone presenting with the above features of chiasmal syndrome should be investigated with urgent neurological imaging, in order to promptly diagnose and, if necessary, treat a potentially life-threatening cause.

Definition

Optical art (or op art) was an art movement that emerged in the mid-twentieth century as an extension of the pop and conceptual art movements. It exploits the mechanics of human visual perception to create imagery in the viewer's mind. Op artists used line, shape, flat planes of color, and a two-dimensional format to create works that appear three dimensional and occasionally convey a sense of movement.

Overview

Optical or op art emerged as an extension of the pop art and conceptual art movements, both of which represented the transition from modernism to postmodernism, during the middle of the twentieth century. From a theoretical perspective, modernism rejected the accepted and established art forms but eventually became formulaic, prescriptive, and predictable, while in response, postmodernism became characterized by a more pluralistic, eclectic, diverse, and somewhat more unpredictable approach to art.

Op art “exploits the workings of perception to create a virtual reality in the viewer's mind” ([1], p. 178). Op artists aimed to create optical illusions using line, flat planes of color, and a two-dimensional format to create works that appear three dimensional and occasionally convey a sense of movement. Characterized by an emphasis on geometry, simple forms, and a strategic color ► [palette](#) (often black and white or strong contrasting colors), op art also represented “geometric precision, emblematic not only of the Space Age but... (also the) technological revolution” of the 1960s ([2], p. 73). Color and light–dark contrast are dominant visual elements in op art and used strategically to create three-dimensional visual illusions from two-dimensional formats. In addition, the strategic use of color was applied to create a sense of movement across the canvas or painted surface, and in this way, op art paintings represent outcomes that are more than the sum of their parts in terms of applied paint on surface.

Optical Art, Fig. 1 Works by Victor Vasarely

Optical Art, Fig. 2 Works by Bridget Riley

Op artists often embedded known illusions or optical effects into their works such as simultaneous contrast and colored after-images, the Hering illusion, café wall illusion, scintillating dot illusion, and the Muncker illusion.

Although she does not like the title “op art,” Bridget Riley’s works are closely associated with this movement as well as “the spirit of the mid-sixties”; and Victor Vasarely’s works are reflect the visual aesthetics of the op art movement ([2], p. 72).

Victor Vasarely (1906–1997)

Op art works by Hungarian-French artist Victor Vasarely feature the illusion of three dimensionality, and this is achieved by the strategic placement of geometric shapes, color, and contrast upon the canvas. Vasarely first started to experiment with optical patterns in the 1930s and his works were included in the Museum of Modern Art’s exhibition: *The Responsive Eye*. This exhibition, which also included works by Bridget Riley, featured

works that which were considered “less as objects to be examined than as generators of responses in the eye and mind of the viewer” ([3], p. 1). The works included in this exhibition featured works that used optical illusions, simultaneous contrast, and afterimages to produce “new kinds of subjective experiences” ([3], p. 1). As a prolific painter, key works by Vasarely include *Vega Nor* (1969), *Vega III* (1957), and *Marc Positive* (1968) (Fig. 1).

Bridget Riley (Born 1931)

Works by English painter Bridget Riley feature the illusion of three dimensionality, and this is achieved by the careful placement of variations in shape as well as color or light–dark contrast. In addition, Riley’s works often feature a sense of movement, and this is achieved by the strategic placement of color around the canvas, causing the viewer’s eye to be drawn from dominant colors and contrasts around the canvas. Figure 2 features Riley’s *Movement in Squares* (1961), *Hesitate* (1964, Tate), and *Nataraja* (2000, Tate).

The art movements of op art as well as minimalism and pop art had a strong influence on popular culture as well as fashion design in the late 1950s and 1960s [4–8]. Design output by Mary Quant, André Courreges, Pierre Cardin, and Terence Conran and firms such as Marimekko are imbued with design characteristics drawn from op art and pop art. In addition, op art influenced additional diverse sectors within applied design including graphic design and an early example is the International Wool Secretariat logo by Francesco Saroglia (1965).

An artist who often harnessed illusions or optical effects into his works was Venezuelan Carlos Cruz-Diez (1923–2019). A number of small and large scale works by Cruz-Diez feature simultaneous contrast or colored after-images, and two examples include *Induction du Jaune, Série Nov 06/5* (2006) and *Induction Chromatique à double fréquence* (1993). Simultaneous contrast occurs when the perception of a color is influenced by surrounding color and colored after-images occur when color arrangement and viewing time prompts an illusion of color.

More recently, artists like Olafur Eliasson (b. 1967) have created installations and artworks that feature similar optical art effects often on a larger scale. For example, Eliasson's "Room for one color" (1997) features an immersive environment saturated with yellow light. The effect prompts a range of perceptual effects for viewers, notably changing the perceived color of objects and creating a strong after-image color on leaving the art installation [9].

Ostwald, Friedrich Wilhelm

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Wilhelm Ostwald was born on September 2, 1853, in Riga, the capital city of Latvia, to parents of German descent. He studied chemistry at the University of Dorpat (now Tartu, Estonia) where he received his PhD in 1878 and lectured at the Polytechnicum in Riga. In 1887, he moved to the University of Dresden in Germany where he remained until his early retirement in 1906. He was active in many fields, including philosophy, is considered to be one of the founders of physical chemistry, and received the Nobel Prize for the discovery of chemical catalysis in 1909. Ostwald is the author of 45 textbooks and over 1000 articles. In his spare time, he was a talented painter. In 1905/1906, he spent several months in the Boston area giving courses in philosophy, physical chemistry, as well as techniques of painting at Harvard University, MIT, and the Lowell Institute, where he met Munsell and learned of the latter's early development of the Munsell color system. After

he left the University of Dresden, he moved to his nearby countryseat in Grossbothen where he spent the rest of his life primarily working on color theory and developed a large color order system and a theory of color harmony. Ostwald died on April 4, 1932 Grossbothen [1].

Major Accomplishments/Contributions

In the total field of science, Ostwald saw the place of the science of color to be in psychological science [2]. He was not only fully aware of the work of Maxwell, Grassmann, and Helmholtz but was convinced that also Hering had made important contributions toward understanding of color phenomena. His immediate predecessors had focused primarily on the relationship between lights and color experience. Ostwald made significant contributions to the understanding of object colors. His main contributions in the color field are briefly mentioned below:

Color order system: Ostwald developed a color order system that combined psychological and psychophysical knowledge, resulting in *Grosser Farbenatlas* of 2500 systematically ordered samples published in 1917/1918 (Fig. 1). A reduced version of 600 samples was available in 1920. An American version of the system was published in the 1940s as *Color Harmony Manual* [3].

Ostwald, Friedrich Wilhelm, Fig. 1 View of the double cone model of Ostwald's color atlas

Distinction between unrelated and related colors: Helmholtz and others of his time investigated color primarily in terms of spectral light. Ostwald demonstrated and clarified the difference between unrelated and related colors, the latter experienced from viewing objects in varying surroundings. He showed that colors such as gray, brown, olive, and others exist in related form only [2].

Nonlinear relationship between wavelength differences and perceived hue differences: Ostwald demonstrated the highly nonlinear relationship when establishing the hue circle of his color atlas, showing that there are two spectral regions where perceived hues change rapidly as a function of changes in wavelength, while near the beginning, middle, and end of the spectrum, the frequency of change is much reduced [4].

Farbenhalb/Vollfarben: Ostwald demonstrated that idealized complementary object colors have reflectance in half of the spectrum in one case and the other half in the other case, with the transition wavelength varying as a function of hue. He used the term *Farbenhalb* (half of the spectrum) for this situation. He used a graphic format with wavelength on the horizontal and reflectance between 0 and 1 on the vertical axis. Object colors represented by *Farbenhalb* he named *Vollfarben* (full colors), object colors of the highest saturation possible for a given hue, occupying spectral ranges with either one or two transitions in the

spectrum. Full colors are the optimal object colors of a given hue at the lightness level at which they have highest saturation, varying by hue. In 1920, Schrödinger offered a mathematical proof of the concept of optimal object colors that included Ostwald's *Vollfarben* [4].

Metamerism: In 1918, Ostwald demonstrated the existence of metameric object colors and introduced the term *metamerism* [4].

Textbooks on color: During his lifetime, Ostwald published several volumes on color. The most important ones are part of a planned five-volume work *Die Farbenlehre* (The Science of Color), of which only two volumes were published during his lifetime: Vol. I *Mathetische Farbenlehre*, 1918 (ordering of color), and Vol. II *Physikalische Farbenlehre*, 1919 (color physics).

Definition

1. Board on which paints are set in order to mix them before applying to a painting
2. The color range or selection used in a composition, art work, or design object

Introduction

In its narrowest sense, a painter's palette is a rigid board on which a set of paints is laid out and adjacent to which is an area where its ingredients can be mixed before application to a canvas, board, or other support. In its widest sense a palette represents any range of colors an artist or designer has chosen for use in any specific project. For some tasks this may simply mean black and white with various greys mixed from them; for others it can

mean an array of dozens of colors, with others mixed from them. For centuries, the palette has been an essential item in every painter's studio. Since the appearance of the Quantel Digital Paintbox (1981), many artists have replaced the paintbrush with the computer mouse, though the term "palette" is still retained to refer to the range of colors available for introduction into the visual image.

Palette, as a Board for Arranging and Mixing Paints

European palettes were traditionally made of hard wood (such as mahogany or walnut) and weighted or shaped in order to balance comfortably on the wrist or forearm of the painter while working. From about 1400, a number of portraits show small wooden palettes with handles either laying flat on a table or propped up beside a set of brushes, commonly one for each color. The latter has corners to stop them rolling over and also imply viscosity in the paint being used. For larger works, and less viscous paint, shallow bowls of single colors and large brushes were used. After about 1500, for easel paint in either tempera or oil, a palette large enough to accommodate about a dozen colors is pierced in one corner by a thumb hole. After about 1600, large curved palettes that rest on the forearm become general and define a design that remained standard into the twentieth century, though smaller, rectangular palettes that fitted into the lids of paintboxes also continued to be used. Throughout the ages, many other materials have been employed to hold and mix paints, including shells, porcelain, glass, metal, plastic, or bone, as in the case of the scapula palettes of prehistoric times. Metal trays or containers are best for wax or encaustic painting (requiring heat), and glass jars are useful for fresco painting. Shallow, cupped palettes are suited to dilute egg tempera and watercolor paint, whereas flat boards are ideal for holding small quantities of oil, alkyd, and polymer paints.

Palette as a Color Range or Selection

The common function of a palette (whatever its size and format) is to reveal the selection of

chosen colors at a glance and assist the painter in working with a degree of speed and efficiency. According to Giorgio Vasari (1568), Lorenzo di Credi (a fellow-pupil of Leonardo in the studio of Andrea del Verrocchio) "made on his palettes a great number of colour mixtures, so that they went gradually from the lightest tint to the darkest, with exaggerated and truly excessive regularity, so that sometimes he had 25 or 30 on his palette, and for each of them he kept a separate brush." More often, color mixing was kept to a minimum, and colors employed in the glorification of gods were kept as pure and unsullied as possible.

Historical Development of Palette

Of the many reference sources that document the historical variation and content of artists' palettes, among the more informative are Letalle's *Les palettes d'artistes* [1], Speed's *The Science and Practice of Oil Painting* [2], Schmid's *The Practice of Painting* [3], Bazzi's *Abecedario pittorico* [4], and Birren's *History of Color in Painting* [5].

Ancient Times

The limited range of the pigments used by the earliest painters can be ascertained from cave paintings from about 15,000 BC that have survived in northern Spain and western France. The palette employed is known to have included red ochre (hematite), yellow ochre (limonite), stibnite (grey antimony sulphide), and kaolin (white aluminium silicate). Remarkably, this four-pigment palette, known to the Greeks as the *tetrachromatikón*, not only survives in Europe but is found widely scattered throughout the globe, being a common feature in the traditional painting by the Polynesian artists of the Pacific and New Guinea, by many African tribes, and by the Australian Aborigines. Reds, greens, and yellows from vegetation may have been used but generally rapidly fade.

Ample evidence remains of the contents of the ancient Egyptian palette. In addition to fugitive dyestuffs, the Egyptians employed gypsum (calcium sulfate), white lead (lead carbonate), red lead (lead oxide), realgar (arsenic disulfide), orpiment (arsenic trisulfide), malachite green and

azurite blue (two forms of copper carbonate), Egyptian blue (crystalline copper silicate), and various carbon blacks, including lamp black and bone black. Egyptian Blue has been identified in painted decorations from about 2500 BCE onward, and its manufacture combined chalk or limestone with sand and a copper mineral, such as azurite, fired in a kiln at precise temperatures. Lapis lazuli was used in jewellery but is unlikely to have been employed as a pigment at this time.

In ancient Greece, the practice of intermixing the four earth colors was credited to the painters Polygnotus and Anaglaophon. The reliance on a palette of red ochre, yellow ochre, chalk white, and black (commonly from burnt wine lees) caused Pliny to remark, in his *Natural History* (37.12): *Quattuor coloribus solis immortalia illa opera fecere* (“Four colours alone to make their work immortal”). Apelles was acknowledged as the principal advocate of the tetrachromatikón, from which all human complexion colors could be obtained, plus the browns of hides and fur, and even the dull greens of foliage, when yellow ochre was mixed with bluish black. Additionally, Pliny writes of Apelles applying varnish to his paintings that “caused radiance in the brightness of all the colours and protected the painting from dust and dirt.” Pliny also makes a distinction between the “austere” colors (*austeri*) of the “four-earth” palette and vivid or “flowery” colors (*floridi*). Among the latter are red lead (minium), purpura lake (purpurissum), dragonsblood (cinnabaris), Armenian blue (azurite), chrysocola, and Indigo.

Greeks and Romans used much the same palette, adapted from the Egyptians, and the only significant pigment introduced by the Romans was cinnabar (natural mercuric sulfide).

Medieval Age

After the fall of the Roman empire (about 400 CE), few surviving records refer to the constitution of artists’ palettes, owing perhaps to illiteracy or a desire to keep certain practices secret, or simply because processes were so well known that no one felt the need to write them down. Commissions and contracts might specify which pigments were to be used for particular artworks,

usually with the aim of preventing the substitution of inferior colorants for precious ones similar in color, such as red lead for vermilion, or azurite for lapis lazuli, which at its finest was worth its weight in gold. The English word “guarantee” comes from the Italian term *garanza*, referring to genuine madder dyestuff. Where instructions for selecting raw materials, preparing paints, and the correct methods of using them were recorded, it was usually in the form of secret recipe books known as formularies. One of the most informative of these is *De diversis artibus* (“On diverse arts”) by the monk Theophilus (Roger of Helmarshausen), who also describes a formula for preparing artificial vermilion and whose *Schedula diversarum artium* also describes procedures for illuminating manuscripts.

An unusually complete formulary that has survived from the early Renaissance was compiled about 1400 by the Tuscan artist Cennini Cennini. Whereas Leon Battista Alberti’s treatise on painting (1435) is largely theoretical, and refers only briefly to color mixing, Cennini’s contains over 150 short chapters covering numerous aspects of workshop practice. It describes, for example, a relatively new yellow made from lead and tin oxides heated to 800°. Cennini calls it *giallorino* and describes it as heavy and permanent and useful for painting foliage and grass. In English, it became known as massicot (and subsequently lead-tin yellow) and was sometimes glazed with Indigo for depicting foliage.

Medieval artists also learnt that palettes could be extended when raw earths were roasted or calcined. Hence, yellow ochre was transformed into a reddish pigment variously called burnt ochre, light red, or English red; raw sienna and raw umber became burnt sienna and burnt umber, the latter useful for flesh tints. During the Middle Ages, a typical workshop palette might therefore include white lead, kaolin, gypsum, massicot, orpiment, yellow ochre, burnt ochre, red lead, raw sienna, burnt sienna, raw umber, burnt umber, red ochre and red bole, cinnabar or vermilion, madder lake, brazilwood lake, green earth, sap green, verdigris, malachite green, azurite blue, flower of woad, genuine ultramarine, lamp black, bone black, and vine black.

Renaissance and Beyond

Though Hubert and Jan van Eyck were not the inventors of oil painting, they are acknowledged (e.g., by Filarete) as perfecting its use in pictorial painting, together with Rogier van der Weyden. Antonello da Messina is often credited with introducing the medium into Italy, and by the end of the 1400s, oil painting was commonplace throughout Europe. Magnificent frescoes continued to be painted throughout the 1500s, notably by Raphael, Michaelangelo, and Annibale Carracci, but working from a handheld palette distributed with oil colors became almost universal practice from the mid-sixteenth to the mid-twentieth century, when North American abstract artists in particular began making large-scale abstract works. At the same time, commercial paints, alkyds, and acrylic paints stimulated new and bolder methods of working. Notable exceptions were the various schools of watercolor painters, who devised small, portable, and often ingenious palettes for outdoor sketching and made of either wood or lightweight metal.

Baroque and Classicism

With the decline in large commissions from the church, courts, or guilds, and the rise of the merchant class, it became more difficult for aspiring artists to become pupils and apprentices in large-scale workshops. To compensate for this, from the late 1600s onward, a series of books began to appear that offered tuition in the basic skills of assembling and applying practical palettes. Among the first was William Salmon's *Polygraphice* (1672), followed by Claude Boutet's *Traité de la mignature* (1673), modified through dozens of editions. Alternatively, a student might learn from a single master but had better chance of a more rounded education if he could enroll at one of the many new academies, though even in the 1700s, these were few and far between. Italian painting continued to be much admired, and writers often bemoaned the fact that artists like Titian had not passed their "secrets" of color-mixing down to later generations, though Lomazzo's *Trattato dell'arte de la pittura*

(1584) had preserved some of the late-Renaissance practices.

The glazing of three primary colors, demonstrated in color circles, was included in Moses Harris' *Natural System of Colours* (1766), offering a new concept of tricolor mixing, and extended in Johann Lambert's *Farbenpyramide* (1772) and James Sowerby's *New Elucidation of Colours* (1809) and culminating in Philipp Otto Runge's three-dimensional *Farben-Kugel* (1810). As the science of chemistry accelerated throughout the early nineteenth century, many new artificial pigments were added to the artists' palette, notably cobalt blue (1804), chrome yellow (1818), cadmium red and yellow (1817), Guimet's artificial ultramarine (1826), and chromium oxide green (1838).

Nineteenth Century

In excess of 50 instructional books on how to use color palettes were published during the 1800s, though few influenced the development of fine art painting as such. One exception is Ogden Rood's *Modern Chromatics* (1879), responsible (in its French edition of 1881) for clarifying Chevreul's earlier explanations of optical color mixing. By the mid-1880s, numerous artists (including Georges Seurat, Vincent van Gogh, and Camille Pissarro) were laying out their colors in spectral sequence, with white available for tinting.

Twentieth Century

Over the next 30 years, almost every progressive painter experimented with some form of pointillism, and its novel way of applying unmixed color directly from the palette to the canvas (notably in early twentieth-century French and German expressionism) led to the liberation of color as a pictorial element in its own right, and one no longer restricted to the traditional task of describing forms in the natural or built environment.

During the early years of the twentieth century, avant-garde artists became less concerned with the subtleties of matching their colors to external

objects as with the relationships between the colors arrayed on the palette. Such a preoccupation was reinforced first by the publication of Albert Munsell's *A Color Notation* (1905) and then of Wilhelm Ostwald's *Die Farbenfibel* (1916), which was highly publicized throughout European schools of art and design. One limitation of such systems, and others like them, was their emphasis on opaque colors, whereas many artists (including Paul Klee) typically experimented with translucent oil or watercolor glazes. Additionally, as if in reaction to the color explosion of the Impressionist generation, the Cubists reverted to the ancient tetrachrome palette, with Georges Braque, Pablo Picasso, and even Marcel Duchamp, restricting their palettes to white, black, red and yellow ochre, and subdued green earth. No theorists or writers of art manuals influenced their decision, yet a general reversion to classicism held sway until the mid-1950s, through various realist revivals, until vivid palettes came to the fore again in the 1960s, with the extravert and confident art movements variously labeled Pop Art, Op Art, and ► [Color Field Painting](#).

Palmer, George

Rolf G. Kuehni
Charlotte, NC, USA

Louis Fehr: George Palmer, ca. 1820

Biography

George Palmer, also known as George Giros de Gentilly named Palmer, was an English dye chemist, color theorist, inventor, and soldier. According to his obituary, Palmer was born ca. 1746 on a ship, to English Catholic parents. Due to the eighteenth-century restrictions on activities of English Catholics, Palmer lived a double life between England and France. Nothing is known about his early years. Circa 1775, he introduced a solution of tin as a new mordant for the dyeing of wool fabrics in Louviers, France, using the last name Giros de Gentilly [1, 2]. In 1777, located in London, he published the book *Theory of Colours and Vision*, a French edition of which was published in the same year in Paris, translated by Palmer's friend Denis-Bernard Quatremère d'Isjonval, at the time active in the textile manufacturing facility Disjonval in Sedan,

France, owned by his family [3, 4]. In the same year, Palmer also invented a fawn-colored dye in London [5]. In 1781, J. H. Voigt of Gotha, Germany, editor of *Magazin für das Neueste aus der Physik und Naturgeschichte* (Journal for the Latest Physics and Natural Sciences News), describes meeting with Giros von Gentilly and the latter's conjectures about color blindness [6]. In 1785, Palmer, living in Paris, had *Lettre sur les moyens de produire, la nuit, une lumière pareille à celle du jour* (Letter Concerning the Means of Producing at Night a Light Equal to Daylight) published [7] describing the modification of oil lamplight with a blue glass mantel, a technology that became fashionable for a time. In 1786, Palmer published *Théorie de la lumière, applicable aux arts, et principalement à la peinture* (Theory of Light Applicable to the Arts, Principally to Painting) [8]. Toward the end of that decade, likely as a result of the French Revolution, Palmer became a mercenary soldier in the Corps of Engineers, at different times for Sweden, Austria, and Russia, reaching the rank of major, as described in his obituary [9]. For a time in the early nineteenth century, he lived near Leipzig in Germany where he reported on four technical inventions, one of which being a fire-extinguishing powder, a demonstration of which was reported in a local newspaper. In 1811, Palmer moved to Copenhagen into retirement and died there destitute in 1826 [10].

Major Accomplishments/Contributions

Palmer made lasting contributions to the development of color science by being the first to propose that there are three different mechanisms in the human eye that account for color vision: "The superficies of the retina is compounded of particles [light sensors] of three different kinds, analogous to the three rays of light; and each of these particles is moved by its own ray" [4]. This statement has proved true in regard to the number of different daylight sensor types, the cones, in the human eye, if not in regard to the claim of three

kinds of light. Thirty-five years later, a similar statement was made by the eminent physicist Thomas Young [11].

Voigt, in his report on Giros von Gentilly, describes him as having stated that color blindness arises if one or two of the three kinds of "particles" in the retina are inactive, a statement found to be valid [6]. In 1786, Palmer provided a hypothesis for the complementary nature of the successive contrast effect by stating that it is due to fatiguing of one or two of the light sensor types, an explanation that continues to be accepted as valid, as does his conjecture that the different kinds of sensor take different times to recover upon exposure to strong light [8].

Parafoveal vision

Definition

The parafovea may refer to a position at a visual angle of approximately 4° from the normal fixation point or to the region extending to that angle from the fovea. It is compositionally distinguished from the fovea by its lower cone and ganglion cell densities and by its higher rod density. As may be expected, these differences affect its visual perception characteristics. Its spatial contrast sensitivity, visual acuity, and other visual attributes are lower than those of the fovea, but, as shown by its critical fusion frequency (CFF), its temporal frequency resolution extends to higher frequencies than that of the fovea. Its color perception is essentially the same as that of the fovea, but under low luminance, it becomes similar to tritanopic diachronic perception. These characteristics can be inferred from the relative distribution of the three cone types in the parafoveal retina. In reading, moreover, parafoveal information contributes to line of vision movement and to fine foveal information processing.

Overview

The retinal structure in the central visual field comprises three distinctive regions. As shown schematically in Fig. 1, the parafovea lies between the fovea and the perifovea. The fovea lies in the central region extending from the fixation point to a visual angle of 2.5° radial, the parafovea surrounds it and extends out to 4.2° radial, and the perifovea extends from there to 9.2° radial [1, 2].

Parafovea, Fig. 1 Central visual field on monocular viewing [1, 2]

These demarcations are not strictly defined, but phenomena occurring approximately 4° radial from the normal fixation point are generally referred to as parafoveal.

In the parafovea, the cone density declines from the high concentration of cones in the fovea, the rod density rises from the complete absence of rods in the fovea [3], and the density of ganglion cells, which form the retinal outlet of the optic nerve, declines together with the ganglion cell layer thickness from the high density and thickness of the foveal region [4, 5]. Although the parafovea and the fovea both form part of the macula, they differ significantly in macular pigment density [6, 7]. These structural and compositional differences suggest that they affect parafoveal visual perception.

Spatial contrast sensitivity, a fundamental characteristic of visual perception, is lower in the parafovea than in the fovea. The parafoveal contrast at an eccentricity of 4° is functionally characterized as a spatial frequency band-pass filter, like that of the fovea at 0° , but with lower overall sensitivity [8, 9]. In the region most sensitive to spatial frequencies of 2–8 cycles/ $^\circ$, the parafovea

sensitivity is approximately 1/2–1/3 of the foveal sensitivity [9]. Visual acuity is also significantly lower than in the fovea. In Landolt ring visual acuity measurements, subjects with a foveal visual acuity of 2.0 exhibit a sharply lower visual acuity of 0.3 in the parafoveal region at approximately 4° [10], thus showing that a larger character size is necessary for character deciphering. It has been found that the character size threshold for deciphering increases linearly throughout the foveal region and on out to an eccentricity of 30° [11]. In temporal frequency contrast sensitivity, on the other hand, the parafoveal resolution extends to a higher frequency than the fovea, as measured by CFF (critical fusion frequency) [12].

Parafoveal color perception does not depart from that of the fovea under relatively high illuminance, but under low illuminance, it resembles tritanopic dichromatic perception (small-field foveal vision) [13]. This may be inferred from psychophysical measurements that show nearly the same L- and M-cone ratios in the fovea and the parafovea [14] but extremely low S-cone distribution in the parafovea as compared with its L- and M-cone distributions [6].

Reading experiments on parafoveal information processing have shown that efficient reading requires simultaneous parallel processing of parafoveal and foveal information [15]. Figure 2 shows the foveal, parafoveal, and perifoveal regions in reading with three characters occupying a visual angle of 1° [15]. The foveal region, which involves processing in finer detail, is narrow. It occupies only approximately seven characters, but it receives parafoveal information concerning the position of the subsequent characters, which results in a shift in the line of sight toward them by movement of the eyeball. This

has been confirmed experimentally by having subjects gaze at the fixation point and then showing them a word in the paranoveal region, which immediately elicits a response in which the subjects move the line of sight and read that word.

Three phenomena that have been observed in reading experiments concerning parafoveal information processing are known as skipping, parafoveal-on-foveal (PoF), and preview-benefit effects. The skipping effect consists of skipping every third word or so, which would presumably not be possible without identification of the word via the parafovea. The skipped words are generally short terms such as “to,” “for,” “in,” and “the,” which supports the view that a word’s lexical status contributes to the determination of whether it will be skipped.

In the PoF effect, the occurrence of a parafoveal word that is difficult to understand affects the foveal fixation and thus the field of vision. As noted above, parafoveal processing affects foveal processing, and a low-level PoF effect has been well established in experiments involving the occurrence of unfamiliar character combinations in the parafoveal region. The preview-benefit effect has been observed in experiments in which the word on the parafovea that is subsequently to be subjected to foveal processing is replaced by a related word during the saccade. If the replacement word is related to the original parafoveal word, the fixation on that word by the fovea is shorter and its processing thus faster than if the replacement word is unrelated. Recent studies have indicated that the preview-benefit effect occurs in sentences independently of the initial sentence word, mid-sentence words, and final sentence word.

Parafovea, Fig. 2 Foveal, parafoveal, and perifoveal regions in reading when three characters make up 1° of visual angle [15]

On the other hand, it is proposed that parafoveal information processing takes place in two stages: the first is an orthography-based pre-attentive stage, and the second is an attention-dependent lexical access stage by the results from a display change paradigm experiment [16]. Also, it is reported that the efficient parafoveal pre-processing in reading may require binocular vision by measurement of reading time with reduced binocular input in the parafovea [17].

These three effects and its relation for binocular vision are currently the subject of intense discussion and further findings may be expected.

Pastel Colors

Malvina Arrarte-Grau

Landscape and Color Designer, Environmental Color Design Study Group (AIC), Lima, Peru

Synonyms

[Pale colors](#); [Pastel crayons](#); [Pastel paintings](#); [Pastel sticks](#); [Pastel tones](#); [Soft colors](#)

Definition

The range of pastel colors, usually described as pale, is characterized by high value and low saturation. A more subjective definition of pastel colors addresses them as soft and soothing. In painting, the term pastel comes from the French *pastille* [1, p. 117], meaning small loaf or lozenge, in relation to the characteristics of the stick used as a coloring medium. The noun “pastel” also denotes the artwork produced with pastel crayons. As an adjective, “pastel tones” refer to light, pale, clean colors, with an effect similar to the one produced with pastel crayons.

The Pastel Crayon and the Pastel Technique

The pastel crayon is a compact stick used as a dry coloring medium, which combines a pure powdered pigment and a neutral binding for cohesion and plasticity. A component of calcium carbonate, such as chalk, gypsum, or pumice, is used in the preparation of the stick, resulting in various degrees of hardness and in gradations from the purest to the highly luminous. Hard pastels contain a higher proportion of binder, are sharper, and work for drawings and sketches. Soft pastels usually come wrapped in paper, for they are drier and more fragile.

The pastel technique consists of transferring small granules of color from the crayon to the support, usually textured or abrasive for good adherence. A fixative is required for protection after its application. In pastel paintings, surfaces result extremely opaque as high concentrations of pigment allow no transmission of light to the substrate, and hence, there is also no light reflected from the substrate toward the observer through the pigmented layer.

Given the directness and ease of transference of the medium, as well as its purity and similarity in color to those of the natural ► [pigments](#), pastel impressions served as the first measurement standards in colorimetry [1, p. 117].

But the effects of pastels may also be delicate and vaporous, as the ones produced in sketches and drawings. The pastel technique has the

particularity of being used in layers, with the possibility of adding lighter touches over the painted surface, to be diffused and blended mechanically for a lighter and blurred effect. In comparison to traditional pastel crayons, oil pastels have a more intense outcome.

The Pastel in Art

It is said that pastels originated in France. Leonardo da Vinci referred to them in his *Codice Atlantico* (1495) as “a new dry substance” [2, pp. 63–87]. The Venetian painter Rosalba Carriera and the French artist Quentin de La Tour represent the development of the pastel technique mainly used for portraits during the eighteenth century, with fast and realistic effects. The immediate results offered by this medium, appropriate for movement and landscape paintings, made the pastel technique the preferred art form of the ► [impressionist](#) Edgar Degas in the representation of ballet rehearsals and ballerinas. Eduard Monet used pastels for sketching landscapes scenes in rapidly changing lighting conditions, and Henry de Toulouse-Lautrec, in his color sketches of women in the Paris dance scene. The American Marie Cassat, influenced by Degas, created many of her most important works in this medium. Later, pastel tones became popular in Modern Art for their bright and luminous colors.

Pastel Colors and the Pastel Palette

Pastel colors refer to pale clean luminous nuances. The colors in a pastel ► [palette](#) are different from the colors in a pastel crayon set, for in the latter the consistency of the coloring material allows a variety that surpasses pale and luminous nuances. In subtractive mixing, pastel tones would be obtained by adding white to a base color; in this way, the colors recognized as pastel have whiteness as a common denominator. This particularity results from low chromaticness and no content of black.

In occidental culture, the pastel ► [palette](#) evokes spring, summer, and Easter and has been traditionally used in infant decoration for its

softness and gaiety. Pastel tones are also associated with the light and velvety texture of pastel paintings, as in wool and cotton, sugar icing, and powder eye makeup.

Application in Industry and Design

As in all industries, the production of materials makes the possibilities of color available to the consumer. The pastel palette has been recurrent in fashion trends in commercial wall paint. The preparation of pastel colors in paint, as opposed to that of saturated colors, allows a relatively high proportion of white binder and a lower amount of pigment. In general, it could be said that it is more economical to produce. Additionally, interiors painted in pastel colors withstand the passage of time, as they create a beneficial effect from the point of view of environmental design, granting luminosity to the space.

Pastel colors are eloquent when applied to design and frequently associate with a particular style. These typically reinforce vintage images of the world of fashion, decoration, and architecture, such as artifacts of the 1950s and Art Deco buildings, recalling places as Ocean Drive in South Miami Beach. The Miami Vice series from the 1980s brings to mind memorable lavender suits and pink trousers, from a decade when pastel tones became a trend in architecture, interior design, and product design, ranging from men's ties to motorcycles [3]. More recently, pastel Goth combines black leather accessories and dark makeup with pastel-colored wigs and tutus.

In the food manufactory, traditional sweets containing sugar and/or egg whites, such as Easter eggs, doughnuts, and French macarons are offered in appealing pastel colors. At present, around the world, in search of healthier ingredients, matcha, pitahaya, and a variety of fruits give ice cream and delicate sweets, a healthier and visually attractive appearance, resulting in amazing pastel colors.

The consistent application of pastel color in certain industries addresses its relevance in the definition of style and branding of classical objects as could be a 1955 pink Cadillac or a 1961 turquoise Volkswagen Beetle, or a more accessible mint green Vespa.

This is also the case of logos such as the Tiffany & Co. logo in the so-called Tiffany blue. As a resource in graphic design, pastel colors may be combined with the boldness of shape, taking the advantage of contrast against nuances of higher intensity. Flat design is achieved by using pastels or gray as background to selected letter types and figures, in order to create a legible, clear, and well-balanced composition. In line with that concept, the pastel palette has been used in the production of stationery, as it enhances ink hand-writing and dark lettering. It is also promoted in web design [4] through web stencils, which allow the readability of captions and pictures.

Perceptual Grouping and Color

Daniele Zavagno¹ and Olga Daneyko²

¹Department of Psychology, University of Milano-Bicocca, Milan, Italy

²Department of Psychology, Sociology and Politics, Sheffield Hallam University, Sheffield, UK

Synonyms

[Gestalt grouping principles \(or laws\)](#)

Definition

Perceptual grouping refers to principles by which means a set of physically discrete elements are partitioned into perceptual groups by the visual system, thus forming higher order perceptual units. Perceptual grouping was first studied by Max Wertheimer, one of the fathers of Gestalt psychology [1]. It is a core topic within the studies of perceptual organization, along with figure-ground segmentation [2]. When it comes to color, there are two aspects of perceptual grouping that need to be considered separately: the role of color in perceptual grouping; the effects of perceptual grouping on the perception of color. In the first case, the focus is on how color can direct and/or affect the perceptual organization of a visual scene. In the second case the focus is on how a color is affected by grouping processes.

The Effect of Color on Perceptual Grouping

Perceptual grouping is, along with figure-ground segmentation, a core topic in the studies of perceptual organization, i.e., of those processes that structure the sensory input into coherent units (visual objects, entities, and events), thus contributing significantly to the layout of the visual scene. From such a definition, it is clear

Perceptual Grouping and Color, Fig. 1 Grouping by color similarity. (a) Gray dots organized in a regular square lattice within which no other group or visual structure emerges. (b) By selectively introducing a change of color in some of the dots one can generate specific patterns; (c) notice that the strength of the pattern is directly influenced by the color similarity of the dots: in this lattice, 30% of the dots that form the arrow are made of colors other than yellow, and the impression of an arrow-like structure is weakened. (d) This lattice is made of round and square dots; because of shape similarity the lattice appears vertically organized in pairs of columns; (e) color similarity can overrun shape similarity, switching the perceptual organization from columns to rows. (f) This pattern would normally appear as dots organized in columns according to the factors size similarity and proximity; by introducing color, another pattern within the pattern appears. (g) Because of

proximity, the configuration normally appears organized in horizontal rows (right side); color similarity, however, overruns the factor proximity forcing a perceptual organization in vertical columns (left side). (h) Number 4 appears in spite of proximity and good continuation; notice, however, that in this configuration and the one in (e), the red patterns can be seen as if they were under the lattice, an impression that recalls transparency. (i) Color similarity does not disrupt good continuation; instead it generates a second order group because of which the interception between the curvy line and the straight line becomes a salient feature of the configuration. (j) On the left the factor closure determines the impression of a circle with a red arch; on the right, the red arch is grouped with other red ones, masking the completion effect. Notice, however, that in this last case the light blue circle appears to complete amodally under the structure formed by the red arches

that *grouping* and *segmentation* are two faces of the same coin, as originally postulated by the fathers of Gestalt psychology Max Wertheimer, Wolfgang Köhler [3], and Kurt Koffka [4].

The main factors that regulate perceptual grouping are the following: *proximity*, *similarity*, *common fate* (similarity in motion or change in time), *good continuation*, *closure*, *prägnanz* (or *good Gestalt*, or *structural coherence*), and *past experience*. These factors are also known as Gestalt “principles” or “laws.” Color comes into play with the factor *similarity*. Figure 1a shows a regular square lattice of dots; these can be grouped in many ways to form subpatterns, yet none of the resulting patterns is specific to the lattice, nor are they durable perceptions. By selectively introducing a color difference between the dots, the visual system can be forced to organize the dots of the

lattice into stable patterns or to form larger units based on color similarity. Figure 1b, for instance, shows a yellow arrow; notice, however, how the grouping effect weakens if the dots that make the arrow in Fig. 1b show instead multiple colors as in Fig. 1c. Color similarity is a relatively strong factor that can overrun other types of similarities, such as *shape* (Fig. 1d, e) and *size* (Fig. 1f). It can also overrule a relevant factor such as *proximity* (Fig. 1g, h); however, it cannot easily overrun *good continuation* (Fig. 1i). Finally, while color differences among elements do not seem to affect closure (Fig. 1j left), grouping by color similarity can be employed to mask closure (Fig. 1j right).

As a grouping factor, color similarity is not “all or none” (Fig. 2): this makes color similarity an extremely ductile tool in art, art restoration, design, cognitive ergonomics, etc. as it can be

Perceptual Grouping and Color, Fig. 2 Grouping by color similarity is not all-or-none: in (a) the light green and the dark green dots are grouped separately in substructures that are then combined together to form the impression of a global ray fish-like structure. In (b) dots are of three different shades of green, loosely organized with brighter greens at the center and darker greens in the periphery of the ray fish-like structure. This type of grouping is commonly observed in pictorial art and can be easily appreciated in the art movement known as Pointillism. The case

represented in (c) is somewhat similar to the one shown in Fig. 1c; however, here the ray fish-like structure emerges more easily because of the limited number of colors used and the way they are ordered, with the green dots grouped in the center, the yellow ones surrounding the green dots, and the red dots delimiting the periphery. This kind of grouping can be exploited to show energy patterns (for instance, patterns of neural activation, intensity distributions, etc.)

used to enhance, impose, or create visual structure or to hinder or mask the perception of structure, form, such as in animal mimicry or in military camouflage.

The Effects of Perceptual Grouping on Color

More problematic is the account of the effects of perceptual grouping on color. In an early paper, Fuchs [5] described situations in which perceptual grouping lead to color assimilation. Though sometimes reported by different authors (see for instance [6, 7]), older books dedicated to color perception [8, 9] curiously do not make mention to Fuchs' findings on color assimilation and grouping. The issue may depend on the fact that Fuchs' demonstrations do not always work on paper (or screen), maybe because they were mostly created by using light, shadows, projections, and reflections.

An attempt to graphically replicate one of Fuchs displays is made in Fig. 3a, b, in which two identical gray dots are placed one at the center of a square made of four blue dots and the other at

the center of a square made of four yellow dots. According to Fuchs, the gray dot surrounded by blue dots should appear bluish, while the gray dot surrounded by yellow ones should appear yellowish. The impression, however, though rather weak, seems to go in an opposite direction: that of contrast, at least as far as lightness (achromatic surface color, Fig. 3c, d) is concerned. Figure 3e, f employs proximity and good continuation to create two rows of respectively yellow and blue dots, which both incorporate an identical green dot: for those who will get an assimilation effect, the green dot grouped with the yellow dots will look somewhat more yellowish (or *warmer*) than the green dot grouped with the blue ones. It is not uncommon, however, to have observers reporting an opposite finding, or the same observer reporting switches from assimilation to contrast and vice versa.

While the perceptual outcomes emerging from the observation of Fig. 3e, f are not clear, those deriving from Fig. 3a, b recall the effects of perceptual grouping on lightness [10]: a middle gray target that is grouped with dark gray surfaces will look lighter than a middle gray target that is grouped with light gray surfaces (Fig. 3c, d).

Perceptual Grouping and Color, Fig. 3 (a, b) A graphic interpretation of one of Fuchs' displays: the central gray dot should appear bluish when surrounded by blue dots and yellowish when surrounded by yellow dots. (c, d) A typical lightness contrast effect due to perceptual

grouping and accountable in terms of the anchoring theory for lightness perception [6]. (e, f) Two straight lines of dots (proximity, good continuation), one yellow and the other blue, both including a green dot. Similar configurations can give rise to either assimilation or contrast

Perceptual Grouping, Belongingness, Assimilation, and Contrast

Was Fuchs completely wrong when he wrote about color assimilation as an effect of grouping elements into meaningful wholes? As mentioned earlier, his experimental setups were quite different from those commonly used nowadays, hence before any conclusion can be drawn his experimental setups need to be replicated. Moreover, Fig. 4 may be considered in support of Fuchs claims, who insists on the idea of assimilation as a reduction of differences among the parts grouped to form a Gestalten. In Fig. 4, the two configurations made of zebra-like structures, derived from a modification of a well-known graphic artwork by Victor Vasarely, show strong effects of color assimilation in which not only the "critical" color (to use Fuchs terminology – in Fig. 4a green stripes, in Fig. 4b red ones) assimilates chromatic qualities of the stripes with which they are grouped, but also the blue and yellow stripes pickup characteristics of the critical colors. For instance, in Fig. 4a the yellow stripes have a greenish tinge while in Fig. 4b they have a slight orange tinge.

Apart from the difficulties in reproducing Fuch's findings, it is clear that grouping has an effect on color perception, with a perceptual result that, however, may shift from color assimilation to color contrast. This ambiguity may depend on different factors, including a shift of weights

between grouping factors and another relevant Gestalt factor known as *belongingness* [11], which typically supports contrast outcomes in lightness perception. Figure 5 displays an example of the Munker-White illusion [12, 13], which is commonly treated as a contrast illusion governed precisely by belongingness. In Fig. 5c, the grey bars "lying" on the black bars appear lighter than the physically identical grey bars lying on the white ones, thus delivering a result that is similar in direction, but stronger, to simultaneous lightness contrast. Similarly, the green bars on the black ones appear lighter than the green bars on the white ones in Fig. 5b.

If we consider belongingness the major factor responsible for such different appearances in lightness, then one can argue that while in Fig. 4 assimilation is at play, in Fig. 5a contrast is at play despite a certain similarity between the two-color patterns. In Fig. 5a, the top green bars appear yellowish because they contrast with the blue bars on top of which they appear to rest, yet they should be influenced by the yellow bars as they have longer edges in common with the last. In fact, one might still want to argue in favor of assimilation, by maintaining that the yellowish green seen in Fig. 5a is due to an assimilation process determined by the adjacent yellow bars. It is a possibility that, however, clashes with the perceived depth structure of the configuration. When one's attention passes from the top yellowish green bars to the darker and somewhat bluish

Perceptual Grouping and Color, Fig. 4 Colored zebras chromatically modified from one of Vasarely’s graphic artworks. (a) The green stripes appear yellowish on the yellow-striped zebra, while they appear bluish on the blue striped zebra. (b) The red stripes appear with an orange tinge on the yellow-striped zebra, and slightly purplish on

the blue-striped zebra. Moreover, the assimilation effect works both ways: the yellow and blue stripes in (a) appear with a green tinge, while the physically identical yellow and blue stripes in (b) appear to be affected by the red stripes

Perceptual Grouping and Color, Fig. 5 Examples of the Munker-White illusion [12, 13]. In (a) the green bars on top usually appear as lighter and yellowish than the green bars below, which appear darker and somewhat bluish. The configuration is ambiguous as the figure-ground status of the yellow and blue bars change depending on where one fixates. By fixating on the red dot, it is possible also to see one of the two groups of green bars unify to form a semitransparent rectangle. In (b) the effect of contrast is

evident as the lightness of the two sets of green bars change depending on their belongingness to either the black or the white bars. (c) It shows a classic White’s illusion, traditionally treated as a contrast effect. In (d), having split the figure into two, the spatial ambiguity that characterized (a) is no longer present: in the top configuration, the blue bars unify amodally behind the yellow ones to form a blue background on top of which a yellowish green rectangle is seen; in the configuration below the opposite is seen

green bars below, then reorganization of the visual field is experienced due to a process known as *amodal completion* [14]: the visual system groups the two sets of green bars to form two green horizontal rectangles placed one on a uniform blue background, the other on a uniform yellow

background. The bars that do not unify into a continuous surface appear as occluders standing in front of the background and its green rectangle. Because of such grouping processes, Fig. 5a results in a sort of *impossible figure*, with yellow and blue bars changing their figure-ground status

as one inspects the configuration from top to bottom and vice versa. The visual system may attempt to overrun such figure-ground ambiguity by generating a feeble transparency effect, for example, by grouping the top green bars to form a semitransparent rectangle (focusing on the red dot may help see such visual solution). However, this semitransparency, when perceived, does not change the tinge of the green under observation. The shift from the role of figure to that of ground of the yellow and blue bars is instead clearly evident in Fig. 5d, stemming the roles of both grouping principles and belongingness on the appearance of the green bars.

Philosophy of Color

Barry Maund

Department of Philosophy, The University of Western Australia, Crawley, WA, Australia

Definition

The philosophy of any live topic is a matter of puzzles and problems and debates about their solution. Philosophical debates about color go back to the ancient Greeks, e.g., to Plato, Aristotle, the early atomist Democritus, and many others, and they are still alive. One of the most important reasons why colors are of philosophical interest is that they raise serious metaphysical issues, concerning the nature both of physical reality and of the mind. Central among these issues are questions concerning whether color is part of a mind-independent reality or not and what account can be given of experiences of color.

The Scientific Tradition

Serious thinking about color raises important philosophical puzzles and questions. One of the major problems with color has to do with fitting what people seem to know about colors into what science, particularly physics, tells about physical bodies and their qualities. It is this problem that

historically has led the major physicists, who have thought about color, to hold the view that physical objects do not actually have the colors people ordinarily and naturally take objects to possess. Oceans and skies are not blue in the way that people naively think, nor are apples red (nor green). Colors of that kind, it would seem, have no place in the physical account of the world that has developed from the sixteenth century to the twenty-first century.

Not only does the scientific mainstream tradition conflict with the commonsense understanding of color in this way, but as well the scientific tradition presents a very counterintuitive conception of color. There is, to illustrate, the celebrated remark by the eighteenth-century philosopher David Hume: “Sounds, colors, heat and cold, according to modern philosophy are not qualities in objects, but perceptions in the mind” [1]. Physicists who have subscribed to this doctrine include the luminaries: Galileo, Boyle, Descartes, Newton, Young, Maxwell, and Helmholtz. Maxwell, for example, wrote: “It seems almost a truism to say that color is a sensation; and yet Young, by honestly recognizing this elementary truth, established the first consistent theory of color” [2].

This combination of color eliminativism – the view that physical objects do not have colors, at least in a crucial sense – and color subjectivism – the view that color is a subjective quality – is not merely of historical interest. It is held by many contemporary experts and authorities on color. S. E. Palmer, a leading psychologist and cognitive scientist, writes:

People universally believe that objects look colored because they are colored, just as we experience them. The sky looks blue because it is blue, grass looks green because it is green, and blood looks red because it is red. As surprising as it may seem, these beliefs are fundamentally mistaken. Neither objects nor lights are actually ‘colored’ in anything like the way we experience them. Rather, color is a psychological property of our visual experiences when we look at objects and lights, not a physical property of those objects or lights. The colors we see are based on physical properties of objects and lights that cause us to see them as colored, to be sure, but these physical properties are different in important ways from the colors we perceive. [3]

The examples of authorities who say similar things can be multiplied, e.g., W. D. Wright, E. H. Land, S. Zeki, and R. G. Kuehni. It should be noted, in passing, that there is considerable variation in how the subjectivist component is expressed, with colors being variously described as sensations, psychological properties of visual experiences, mental properties, representations, constructions of the brain, and properties of the brain.

The Complexities of the Scientific Tradition

The traditional scientific thinking on color is more complex, however, than has been presented so far. Central figures such as Descartes, Boyle, and Locke think that there are no colors in the physical world – no colors, as people ordinarily and naively understand them to be. But they also speak of colors as *secondary qualities*, i.e., as powers or dispositions, in bodies, to cause experiences of a certain characteristic type. It is instructive to try to understand this dual position.

It was common for such theorists to make a distinction between colors as they are in physical bodies and colors as they are in sensation. And then, with respect to the first kind of color, they made a distinction between a philosophical way of thinking and the common, everyday way of thinking of such qualities (which Newton describes as “such conceptions as vulgar people would be apt to frame”). As Descartes explains, the ordinary way involves the mistake of “judging that the feature of objects that we call ‘color’ is something ‘just like the color in our sensation’” or of believing that “the self-same whiteness or greenness which I perceive through my senses is present in the body.” The philosophical way of thinking, by contrast, is illustrated in his following remark: “It is clear then that when we say we perceive colors in objects, *it is really just the same as saying* that we perceived in objects something as to whose nature we are ignorant but which produces in us a very clear and vivid sensation, what we call the sensation of color” [4].

So, there is a way – a philosophical way – of thinking of objects as having colors. However, three things are important: (1) it is different from the ordinary way of thinking; (2) it involves a revision, or a reconstruction, of people’s ordinary thinking about color; and (3) it presupposes a notion of “sensation of color” or “color as it is in sensation.” It is crucial how this last notion is understood.

It should also be noted, however, that such theorists as Descartes, Boyle, and Locke sometimes wrote, as well, of colors in physical bodies as those features (“textures”) which grounded the associated powers/dispositions to induce the relevant experiences (sensations). Some commentators think that, in so doing, these theorists were either inconsistent or muddled or found it difficult to make up their minds. However, if Descartes, Boyle, Locke, etc., are in the business of revising or reconstructing ordinary concepts, there is no particular reason why they should not introduce several new concepts to replace the single old one, each one serving a different purpose.

Indeed, it is instructive to look at the famous passage in which Newton writes of the rays not being colored:

For as Sound in a bell, or musical String or other sounding body, is nothing but a trembling motion, and in the Air, nothing but that Motion propagated from the Object, and in the Sensorium ‘tis a sense of that Motion under the form of sound; so Colors in the Object are nothing but a Disposition to reflect this or that sort of Rays more copiously than the rest; in the Rays they are nothing there but Dispositions to propagate this or that motion into the Sensorium, and in the Sensorium they are Sensations of those Motions under the Forms of Colors. [5]

Here, he writes of the colors in the object, colors in the rays, and colors in the sensorium, by analogy with sounds in the object, sounds in the air, and sounds in the sensorium.

There seems to be a similar spirit that inspires modern theorists such as Leo M. Hurvich and D. L. MacAdam. These are color scientists who have stressed the existence of a variety of senses of color terms. Hurvich begins the second chapter of his *Color Vision* with the question “What is color?” which he turns into a series of questions:

Is color something that inheres in objects themselves? Is it related to the light falling on an object? Is it a photochemical event that occurs in the receptor layer of the eye? Is it a neural brain-excitation process? Is it a psychical event? Hurvich’s answer is “Color is all these things” [6]. MacAdam writes:

The term color is commonly used in three distinctly different senses. The chemist employs it as a generic term for dyes, pigments and similar materials. The physicist, on the other hand, uses the term to refer to certain phenomena in the field of optics... Physiologists and psychologists often employ the term in still another sense. They are interested primarily in understanding the nature of the visual process and use the term, on occasion, to denote sensation in the consciousness of a human observer. [7]

One might wonder what unites these various senses of the color terms. Why, that is, should color terms be used to apply to each of these types of conditions or properties – the same terms for each? A plausible answer to this question is the following. If one is interested in the detailed causal mechanisms that underlie color perception, then there is good reason to be interested in different stages of the causal process in which objects cause experience of color: chemists and painters would be interested in the pigments, lighting engineers and physicists would be interested in the light-modifying features of objects, physiologists and psychologists would be interested in the cones and rods in the retinas, other physiologists and neuroscientists would be interested in other neural processes and pathways, and psychologists and philosophers would be interested in the experience of color and in how colors appear. What unites them all is that the theorist is interested, at each stage, in that feature of the stage that contributes to the *perception* of color, i.e., to the way colors *appear*.

Philosophical Responses

Within the philosophical community, there has been a mixed response to the view expressed in this scientific tradition. While some philosophers share key aspects of the view, at least in broad

terms and with certain modifications, there have been many who have rejected the view. There has been strong resistance from many philosophers, both to the eliminativist tendency within the scientific tradition and to the related subjectivism.

One form this resistance takes reflects the fact that each component of this traditional view is very puzzling. One response is to say that color terms – red, blue, purple, orange, yellow, green, brown, etc. – are in order; there are paradigms of colors to which the color terms apply: ripe lemons are yellow, tomatoes and rubies are red, and so on. There is no trouble, by and large, in learning these terms and teaching them in ostensive practices to children and others. Moreover, colors play a central role in so many of human social practices, such as painting, art, fashion, decoration, ceremonial, enjoying nature, etc. In the second place, it is hard to make sense of the claim that colors are properties of sensations or are psychological properties; if they are anything, they are, surely, properties of objects and light sources – of peaches and emeralds, of skies, of rainbows, of glasses of wine, of headlamps, and so on.

This second issue is of key importance. Many color scientists are agreed in thinking that one role for color terms is in application to sensations. As well as the examples already given, it is possible to find, in authoritative texts, definitions like “Color attributes are *attributes of visual sensations*, e.g., hue, saturation and brightness”; “Hue: *attribute of color perception* denoted by the terms yellow, red, blue, green and so forth”; “Brightness is the *attribute of a visual sensation* according to which a given visual stimulus appears to be more or less intense”; etc. However, it is a serious philosophical question as to what is meant by “attributes of sensation” (and likewise “colors in sensation”). There are, for example, different ways of understanding what they are meant to be:

1. Qualities *of* the sensation
2. Qualities presented *in* sensation (or experience)
3. Qualities *represented by* the sensation

Each of these views has had, and continues to have, its champions. Some philosophers have

argued that the first candidate makes no sense, that it commits something like a category mistake. It is interesting that one of the first to argue this way was not a philosopher, but the famous color scientist Ewald Hering [8]. Not surprisingly, perhaps, there are other philosophers who reject this charge. One way to do so is to argue that the perceiver is not aware of the qualities *as qualities of sensations*, even though that is what they are.

One issue that complicates the debates is that psychologists have become increasingly reluctant to use the term “sensation.” For example, modern psychological texts, even ones with titles such as *Sensation and Perception*, tend not to use the term “sensation,” opting for “perception” instead. Indeed, in many of the situations in which traditional color theorists would have used the term “sensation of color,” modern theorists would use such terms as “perceived color” and “apparent color.” Interestingly, examples of both usages can also be found in Newton’s theory. In the famous passage in which he declares that the rays are not colored, “in them there is nothing else than a certain Power and Disposition to stir up a Sensation of this or that Color,” he begins by saying: “The homogeneous light and rays which *appear red*, or rather make objects *appear* so, I call red-making; those which make objects *appear* yellow, green, blue and violet, I call yellow-making, green-making, blue-making, violet-making, and similarly for the rest.”

Accordingly, instead of using the expressions “attribute of sensation” and “sensation of color,” it would make sense to use “apparent color” and “perceived color,” as many theorists currently do, or “color as we see it,” as some philosophers suggest. So, the debates can be framed in terms of the colors objects *appear to have* or *look to have*. The philosophical issues remain, however. The point is that it is a matter of philosophical dispute as to what exactly it is for something to *look blue*, say, (i.e., to *appear blue*). It is plausible that it involves the object causing an experience in the subject, but then the question can be raised with respect to the report, say, about one’s experience of blue, whether that report is describing:

1. A quality *of* the experience
2. A quality which is *presented in* the experience
3. A quality which the experience *represents* the object as having

Not only that, but, supposing that the experience does have representational content, there is a further question as to whether it has other features as well (ones that are open to introspective access). One view is that there are sensory qualities which are presented in sensory experience and which are “projected” onto physical objects. In this way, objects appear to have qualities that they do not actually have. Since this “projection” is not a literal one, it requires explanation of course, but its defenders think that it can be provided. On this theory, the sensory qualities presented in experience also form part of the representational content of the experience. This view is sometimes combined with *color fictionalism*, the view that ordinary color language is a language about properties which objects appear to have (but do not actually have). Objects in the world are such that “it is as if they have the colors.”

Color Realism
